Regenerative medicine

Viral vectors

Gene delivery approach

## ABSTRACT

Gene therapy has converged with bone engineering over the past decade, by which a variety of therapeutic genes have been delivered to stimulate bone repair. These genes can be administered via *in vivo* or *ex vivo* approach using either viral or nonviral vectors. This article reviews the fundamental aspects and recent progresses in the gene therapy-based bone engineering, with emphasis on the new genes, viral vectors and gene delivery approaches.

## 60 1. Introduction

### 61 1.1. Medical need for bone repair and current options

62 Approximately 6–6.5 million fractures are reported per year in  
 63 the United States (Praemer et al., 1992). Although bone tissue  
 64 has regenerative capabilities that enable the self-repair of fractures  
 65 (Pelled et al., 2010),  $\approx 5$ –10% of these fractures result in nonunion  
 66 or delayed union (Praemer et al., 1992). Additionally, large critical-size  
 67 bone defect (one spanning  $>2$  cm) resulting from serious trauma or  
 68 tumor surgery cannot union without bone grafting (Hollinger and  
 69 Kleinschmidt, 1990). Management of such massive defects still poses  
 70 a tremendous challenge for orthopedic surgeons (Tseng et al., 2008),  
 71 partly because the injury impairs blood supply and results in ischemia,  
 72 osteonecrosis, bone loss and ultimately non-union (Buckwalter et al.,  
 73 1996).

74 Currently available materials for clinical bone reconstruction include  
 75 autologous bone grafts, allogeneic banked bone grafts and synthetic  
 76 bone substitutes (Bueno and Glowacki, 2009). Autologous bone grafting  
 77 is considered the gold standard to fill a bone defect (Kimelman et al.,  
 78 2007; Kneser et al., 2006; Marino and Ziran, 2010), but autografting  
 79 may be restricted by donor site morbidity, bone availability and the  
 80 need for bone harvesting procedures (Kneser et al., 2006). Furthermore,  
 81 the repair by autografting is not always satisfactory (Gamradt and  
 82 Lieberman, 2004). Allografting can initiate the healing process and  
 83 recruit cells from the surrounding soft tissue (Smith et al., 2011),  
 84 but the donor shortage and potential risk of disease transmission  
 85 remain to be the major drawbacks of allografting. Conversely, various  
 86 synthetic bone substitutes have been developed (for review see  
 87 Szpalski et al., 2010; Bose et al., 2012), but they are still unable  
 88 to provide an osteogenic capacity as good as the autograft (Bueno and  
 89 Glowacki, 2009).

### 90 1.2. Bone cell types, healing process and vascularization

91 Bone formation entails orchestrated activities by osteoblasts, osteo-  
 92 cytes and osteoclasts (Shegarfi and Reikeras, 2009). Osteoblasts are re-  
 93 sponsible for synthesizing the organic extracellular matrix (ECM) and  
 94 regulating matrix mineralization while osteocytes function in mineral  
 95 homeostasis, mechanical sensing and signaling. Osteoclasts can resorb  
 96 bones and play roles in skeletal growth and bone remodeling  
 97 (Bueno and Glowacki, 2009). Bone formation proceeds through  
 98 either endochondral or intramembranous ossification pathway. Endo-  
 99 chondral ossification is the process by which mesenchymal stem cells  
 100 (MSCs) differentiate toward chondrocytes and produce a cartilaginous  
 101 template, which contributes to longitudinal growth of most bones  
 102 (e.g. long bones). Conversely, intramembranous ossification occurs  
 103 without a cartilage template and contributes to the formation of  
 104 calvarial bone.

105 One critical factor to successful bone formation/healing is vascular-  
 106 ization (Santos and Reis, 2010). New blood vessels enable the  
 107 transport of oxygen and nutrients to the metabolically active callus,  
 108 thus angiogenesis plays crucial roles in the onset of fracture healing  
 109 and promotion of ossification (Santo et al., 2013). Angiogenesis is  
 110 regulated by a variety of growth factors, notably vascular endothelial  
 111 growth factor (VEGF). Exogenous VEGF enhances blood vessel forma-  
 112 tion and ossification and promotes bony bridging (Street et al.,  
 113 2002).

### 1.3. Roles of host immunity on bone healing

114

115 Recently, it was shown that bone fracture healing may be retarded  
 116 by endogenous adaptive/innate immune responses. For instance,  $\gamma/\delta$  T  
 117 cells, the innate lymphocytes involved in tissue repair, can repress  
 118 bone healing by influencing the fate of other responder cells and the ul-  
 119 timate callus formation (Colburn et al., 2009). Pro-inflammatory T cells  
 120 also inhibit the ability of exogenously added bone marrow-derived  
 121 MSCs (BMSCs) to mediate bone repair, owing to interferon (IFN)-  
 122  $\gamma$ -induced down-regulation of RunX2 pathway and enhancement  
 123 of tumor necrosis factor (TNF)- $\alpha$  signaling in the stem cells (Y. Liu  
 124 et al., 2012). Conversely, reduction of IFN- $\gamma$  and TNF- $\alpha$  concentra-  
 125 tions, by systemic infusion of Foxp3<sup>+</sup> regulatory T cells or by local  
 126 administration of aspirin, markedly improves BMSC-based calvarial  
 127 defect repair in mice (Y. Liu et al., 2012). Furthermore, delayed fracture  
 128 healing correlates with enhanced levels of terminally differentiated  
 129 CD8<sup>+</sup> effector memory T (TEMRA) cells in peripheral blood (Reinke  
 130 et al., 2013). These CD8<sup>+</sup> TEMRA cells are enriched in fracture hematoma  
 131 and are the major producers of IFN- $\gamma$ /TNF- $\alpha$ , which inhibit osteogenic  
 132 differentiation (Reinke et al., 2013). These data collectively highlight  
 133 the role of recipient T cells in BMSC-based bone engineering (Y. Liu  
 134 et al., 2012).

### 1.4. Protein therapy and gene therapy

135

136 Successful bone healing/repair requires 4 critical factors that act in  
 137 concert: (1) osteoconduction, (2) osteoinduction, (3) cells that can  
 138 respond to osteogenic signals and (4) vascular supply. Bone tissue engi-  
 139 neering aims to offer these components in order to stimulate bone re-  
 140 generation, either in vitro or in vivo. Osteoconduction can be provided  
 141 by sophisticated scaffold design that permits cell attachment, bone ma-  
 142 trix deposition and bone bridging (for review, see Bose et al., 2012).  
 143 Osteoinduction is often mediated by osteogenic growth factors such as  
 144 bone morphogenetic proteins (BMPs), platelet-derived growth factor  
 145 (PDGF) and transforming growth factor  $\beta$  (TGF- $\beta$ ) (Lieberman et al.,  
 146 2002). Among these growth factors, BMP-2 and BMP-7 have been  
 147 approved by the Food and Drug Administration (FDA) for clinical use  
 148 (Boden, 2005; De Biase and Capanna, 2005). BMP-based therapy is  
 149 superior to the use of autologous grafts alone (Villavicencio et al.,  
 150 2005), but the graft may not suffice to completely heal massive segmen-  
 151 tal defects in long bones. Moreover, recombinant human BMP-2 is
