ABSTRACT

In this paper, we focus on improving the accuracy of wireless localization in wireless sensor networks using information derived from the inertial measurement unit (IMU) in a smartphone and the received signal strength (RSS). We propose an algorithm to relate the RSSs and measurements obtained from the IMU to the coordinates of an indoor robot. To deal with the dynamic nature of fingerprint information in an indoor radio environment, we first use the hierarchical Bayesian hidden Markov model (HB-HMM) to process a time series of RSSs. Unlike other HMM-based methods, the HB-HMM depends only on a single initial hyper-parameter for global optimization. Next, we evaluate the measurements obtained from the IMU to identify the robot's state, which includes the rotating, moving, and bumping states. We used the IMU accelerometers to estimate the velocity. Lastly, a method based on the particle filter (PF) was used to fuse the results obtained from RSS and IMU. Experiments show that our algorithm can achieve better accuracy than related algorithms.

40 1. Introduction

41 Nowadays, users are demanding an increasing diversity of applications from wireless sensor networks (WSNs) [1]. Among 42 these applications, indoor localization has emerged as a key func-43 tion of wireless sensor networks for tasks including target tracking, 44 45 robotics and navigation, smart space, intrusion detection, and inventory management [2]. Presently, most commercial WSNs 46 47 are based on the IEEE 802.15.4 infrastructure, which can be incorporated into an Internet of Things (IoT) architecture with internet 48 protocol version 6 over low power wireless personal area networks 49 (6LoWPAN) [3]. It is widely believed that this will develop into one 50 51 of the more pervasive wireless technologies of the future.

In particular, indoor wireless localization based on received sig-52 nal strength (RSS) in an IEEE 802.15.4 infrastructure has long been 53 a challenging problem [4,5]. On the one hand, RSS information can 54 be acquired internally through the use of a WSN communication 55 device, such that indoor localization based on RSS is an off-the-56 shelf commodity for WSNs. On the other hand, in an indoor wire-57 less environment characterized by non-line of sight (NLOS) and 58 multipath conditions, the distance-RSS conversion model becomes 59 60 inaccurate.

Within an IoT environment, a smartphone can get data from the WSN [3]. Moreover, smartphones currently incorporate a number of inertial sensors, including accelerometers, gyroscopes, and magnetic compasses, within an inertial measurement unit (IMU). The fusion of data derived from RSS and IMU signals can then be employed to avoid the performance limitations associated with RSS alone, and represents a tangible solution for indoor localization in WSNs.

However, the performance of inertial sensors in smartphones is limited. Many studies have focused on using the peak-detection algorithm to analyze pedestrian gait in indoor environments [6]. Less attention has been paid to the more challenging problem of locating and tracking mobile robots or vehicles in an indoor environment using the IMU signals of a smartphone. In this paper, our goal is to enhance the value of WSNs in an IoT environment to provide accurate robot/vehicle location and tracking capabilities, which are of paramount importance for many applications such as smart space and inventory management.

In the field of indoor localization using WSNs, fingerprinting [7], trilateration [8], close-proximity [9], dead reckoning [10], and Bayesian filters [11] are commonly used techniques. Of these techniques, the close-proximity technique is the simplest, where a mobile target is assumed to be located in an area nearest the reference node transmitting the strongest signal. Systems employing this technique can provide only a coarse location and require a

86 high density of reference nodes. In fact, RSS can provide a wider 87 range of information based on logarithmic propagation models. 88 According to theoretical and empirical models, the RSS can be used 89 to establish the distance between the transmitter and the receiver 90 [12]. Then, using trilateration or another range-based technique 91 such as weighted least squares (WLS) [13], Semidefinite program-92 ming (SDP) [14] and Multidimensional scaling (MDS) [15], the locations of mobile devices within the WSN can be estimated. 93

However, the unpredictability of NLOS signal propagation and 94 95 multipath propagation through indoor environments are major 96 challenges in indoor localization. To mitigate the influence of NLOS 97 and multipath errors, fingerprinting techniques have recently been 98 examined. In these techniques, RSS values at specific locations are used as fingerprint information. This is also referred to as a range-99 100 free algorithm. Because RSS patterns are directly mapped out 101 according to specific locations, the measurement errors caused 102 by NLOS and the multipath environment are avoided. However, a 103 significant investment of human labor is typically required to build 104 a detailed map-database. Additionally, some authors have proposed Bayesian filter techniques to accumulate information from 105 106 consecutive measurements. Among Bayesian filters, the extended 107 Kalman filter (EKF) and the particle filter (PF) have been widely 108 used in the field of indoor localization. However, the performance 109 of Bayesian filter techniques depends on a priori knowledge of the 110 statistical distribution of the measurement noise. The dead reckon-111 ing technique incorporates measurements derived from inertial 112 sensors, and has also been used in indoor localization. This tech-113 nique uses an accelerometer to perform distance detection, and then uses a compass for heading direction estimation. While the 114 115 technique requires no infrastructure assistance, the location accu-116 racy is limited by the performance of the inertial sensors.

117 In this paper, we propose an unsupervised learning algorithm, 118 namely HPFRI (HB-HMM and Particle Filter for the Fusion of RSS and Inertial Measurements), which employs the hierarchical Baye-119 120 sian hidden Markov model (HB-HMM) for the RSS time series anal-121 ysis and the PF for fusion of the RSS and inertial measurements 122 obtained from the IMU in a smartphone, for improved accuracy 123 of wireless localization in WSNs. With respect to other localization 124 methods employed in WSNs, the contributions of the present study 125 are as follows:

Because we generate the HB-HMM model of RSS values to estimate the location, and use the information obtained from the IMU which is completely irrelevant to signal propagation in the indoor environment, measurement errors caused by NLOS and multi-path is mitigated.

- Our algorithm is based on unsupervised learning that accumulates information through consecutive observation, and, thus, the RSS value is automatically collected.
- Novel methods are employed to identify the robot state based on IMU information.
- A PF method is employed for the fusion of RSS and IMU data.

The remainder of this paper is organized as follows. Section 2
provides an overview of related localization systems. The problem
statement regarding indoor wireless localization is introduced in
Section 3. Subsequently, Section 4 presents the HPFRI algorithm.
Section 5 discusses the experiments run in indoor scenarios. The
paper closes with conclusions in Section 6.

A number of localization techniques based on RSS and IMU data
have been developed for WSNs. For instance, in response to an initiative for the development of a real-time indoor localization system for tracking people, D'Souza et al. designed the Indoor

People Tracker, an approach that employed the proximity to static 149 nodes in the WSN in conjunction with data obtained from onboard 150 inertial sensors [16]. A multi-hypothesis estimation algorithm 151 based on dead reckoning and Monte Carlo approaches was applied 152 to the Indoor People Tracker, which attained an indoor resolution 153 of 2.5 m. In the field of indoor localization based on inertial sen-154 sors, Bayesian filter techniques have been most commonly used. 155 Correa et al. proposed an enhanced filtering method (Power 156 Threshold Covariance Matrix Tuning, PT-CMT) for indoor localiza-157 tion using a WSN that employed the inertial measurements 158 obtained from a nine-degrees of freedom IMU. The experimental 159 results verified that the system correctly estimated the location 160 of a mobile terminal indoors within an area of around $1 \text{ m} \times 1 \text{ m}$ 161 [17]. Hur et al. proposed a discrete-time H_{∞} filter for indoor robot 162 localization in WSNs based on IMU data and chirp spread spectrum 163 (CSS) ranging [18]. This method improved the ranging precision 164 accuracy to 1 m. Lee et al. proposed an indoor pedestrian localiza-165 tion system equipped both with inertial sensors and the IEEE 166 802.15.4a CSS radio [19]. Experimental results demonstrated a 167 mean error of approximately 1.5 m with five position-unknown 168 beacons. Aimed at monitoring groups of mobile nodes, Franco 169 et al. proposed a data fusion method using information derived 170 from an RSS indicator (RSSI) and an IMU [20]. The Kalman filter 171 and multidimensional scaling were employed to estimate robot 172 dynamics. The error distribution of the system was determined 173 to demonstrate a mean error = 60.3 mm and a standard devia-174 tion = 56 mm. In another study, Tarro et al. proposed a framework 175 based on RSS and IMU data for reducing energy consumption in 176 localization systems [21]. For a given target accuracy, the proposed 177 framework exhibited a lower energy consumption than conven-178 tional methods. 179

However, these approaches did not use unsupervised learning 180 techniques. As such, their performance depended on prior informa-181 tion, which limited their applicability to their initial environments. 182 Wang et al. proposed UnLoc, a self-learning method for indoor 183 wireless localization [22]. By combining dead reckoning, urban 184 sensing, and partitioning based on WiFi into a framework for unsu-185 pervised localization, they established landmarks from various 186 sensors (e.g., accelerometer, magnetometer, sound, and ambient 187 light) to substantiate the position estimate. However, the experi-188 ment did not employ time series data information, and this limited 189 the validation because the transition probability is an important 190 contribution for determining accuracy. 191

3. Problem statement

We consider a WSN deployed in an indoor environment with a193robot equipped with a mobile node and a smartphone. Given this194scenario, we seek to determine the robot's position based on RSS195and IMU data. Specifically, a vector representative of the mobile196node's signal strength received from M reference nodes, namely197the fingerprint, is defined as (1).198

$$S_i = \{s_{i,1}, s_{i,2}, \dots, s_{i,M}\} \quad i = 1, 2, 3, \dots N$$
(1)

Here, *i* denotes the *i*th signal strength sample in the time sequence, 202 as received from the *j*th reference node, and *N* is the total number of 203 samples. For convenience, we divide the indoor environment into 204 grids. If an S_i is given, our goal is to locate the grid that matches 205 the mobile node's position. In our unsupervised fingerprint method, 206 a priori knowledge regarding the positions of the reference nodes is 207 not essential. To save time and labor, in each of K grids we investi-208 gate only a single labeled fingerprint as an initial representative, 209 which is defined as 219

$$F_k = \{f_{k,1}, f_{k,2}, \dots, f_{k,j}, \dots, f_{k,M}\}$$
 $k = 1, 2, 3, \dots, K$ and $j = 1, 2, \dots, M$
