Antidepressants

ABSTRACT

Elevated levels of inflammatory markers, such as C-reactive protein, are well documented in people with depression. Few studies have examined whether the association between inflammation and depression is symptom specific, and differs according to antidepressant treatment. Using data from the English Longitudinal Study of Ageing ($N = 5909$), cross-sectional analyses revealed a significant dose-response association between C-reactive protein and the symptoms of fatigue ($P < 0.001$), restless sleep ($P = 0.03$), low energy ($P = 0.02$) and feeling depressed ($P = 0.04$), but not other symptoms. These associations were absent in users of anti-depressant medication. Our findings suggest the C-reactive protein-depression association is symptom-specific and modified by antidepressant treatment.

1. Introduction

Levels of inflammatory markers, such as C-reactive protein (CRP), are elevated in people with symptoms of depression, although this is not a universal observation (Valkanova et al., 2013). In these studies, depression symptomology is commonly measured with an aggregate score of different symptoms which may mask symptom-specific effects (Valkanova et al., 2013).

Initial analyses into specific symptoms of depression found a significant association between CRP levels with an increased risk that participants reported they had “not accomplished much recently” and felt “like giving up”, but not “often feeling nervous or stressed” (Wium-Andersen et al., 2013). These analyses were not, however, mutually adjusted for other symptoms, so they could be attributed to either somatic (e.g., fatigue) or psychological symptoms (e.g., feelings of low self-worth). In a recent item-level analysis of the US National Health and Nutrition Examination Survey, investigators adjusted these associations for the effect of other depressive symptoms and found CRP was independently associ-

ated with somatic (e.g., reports of tiredness, lack of energy, sleep problems and lack of appetite) but not psychological symptoms of depression (e.g., reports of depressed mood, anhedonia, feelings of self-worth) (Jokela et al., 2016).

We examined these relationships in the English Longitudinal Study of Ageing (ELSA), a population of older people in whom levels of inflammatory markers and the occurrence of depression tend to be higher. Additionally, given that antidepressant drug therapy can have an inflammation-lowering effect (Hannestad et al., 2011), we explore the link between inflammation and specific symptoms of depression according to the use of such medication.

2. Materials and methods

2.1. Participants

Initiated in 2002/03 when study members were 50 years of age or older, the ELSA is an on-going, biennial, nationally representative, multi-disciplinary prospective cohort study of older people (Stephens et al., 2013). Ethical approval was given by the National Research Ethics Service (MREC/01/2/91) and written informed consent obtained from all participants.

For the present analyses, we report on data collected at wave six (2012–2013), when blood samples for CRP and medication use were collected by nurses (Steptoe et al., 2013). A total of 10,601 participants attended the wave six assessment, with 4476 excluded from our analysis owing to missing data on CRP, or incomplete data on depressive symptoms, medication use, or potential confounding or mediating factors ($n = 216$), resulting in a final sample size of 5909 (mean age, 66 years; 54.9% female). Missing values on CRP were due to exclusions placed on participants who had a clotting or bleeding disorder (e.g., haemophilia or low platelets), those who had ever had a fit or convulsion in the last five years, were currently taking anticoagulant drugs (e.g., warfarin), or were unwilling to give their consent in writing for the drawing of blood (Steptoe et al., 2013).

2.2. C-reactive protein

CRP was measured using standard procedures (median, 1.6 mg/L; interquartile range, 0.8–3.2 mg/L) (Bridges et al., 2012) and analysed using the N Latex CRP mono Immunoassay on the Behring Nephelometer II Analyzer (Dade Behring, Milton Keynes, UK). As the original (Shapiro-Wilk test: $V = 2169.78$, $P < 0.001$) and log-transformed ($V = 30.79$, $P < 0.001$) CRP data were originally skewed, we categorized values into quartiles.

2.3. Depressive symptoms

Depressive symptoms were assessed using the eight-item version of the Centre for Epidemiological Studies-Depression scale (CES-D) which has comparable psychometric properties to the full 20-item CES-D (Turvey et al., 1999). Items captured information on whether or not participants had experienced different symptoms of depression, “much of the time” in the past week. Items were categorized according to a 3-factor solution (negative affect, anhedonia, somatic) identified in an analysis of CES-D data across five cohort studies (Carleton et al., 2013). We characterised items loading on negative affect and anhedonia factors as assessing psychological symptoms, resulting in three somatic symptoms (“everything I did was an effort”, “sleep was restless” and “I could not get going”) and five psychological symptoms (“enjoyed life”, “felt depressed”, “happy”, “lonely”, “felt sad”).

2.4. Confounding variables

Information on self-reported physician-diagnoses of autoimmune and inflammatory disorders were recorded (diabetes, rheumatoid arthritis, and coronary heart disease). The use of medications with an anti-inflammatory effect (glucocorticoids and beta blockers), antidepressants and body mass index (BMI) were assessed during a visit to participants' homes by nurses. Antidepressants, glucocorticoids and beta blockers were categorized using the British National Formulary (BNF) 61 (“British National Formulary (BNF) 61 – March 2011”).

2.5. Statistical analysis

We used χ^2 test to examine differences in categorical variables. Depressive symptoms were treated as dichotomous variables (no = 0, yes = 1). We examined associations between quartiles of CRP and individual CES-D items in separate logistic regression models in which effect estimates were adjusted for sex, age, and race/ethnicity, and the sum of the remaining items (to account for the overlap between different depressive symptoms), autoimmune and inflammatory disorders, glucocorticoids and beta blockers (model 1). We then additionally adjusted for BMI (model 2). We tested for a difference in the trend across quartiles of CRP using

orthogonal polynomial contrasts. We then included an interaction term between quartiles of CRP and antidepressant treatment.

A sensitivity analysis using linear regression examined the association between CRP with the sum of the three items assessing somatic symptoms, and also the sum of the five psychological symptoms. All analyses were conducted using Stata 13.

3. Results

3.1. Association between C-reactive protein and depressive symptoms

After adjusting for autoimmune disorders, inflammatory disorders, and anti-inflammatory medication there was an independent, dose-response association between quartiles of CRP and somatic symptoms relating to everything being an effort (odds ratios [ORs] of 1.20, 1.31, and 1.97 for the second, third, and fourth quartiles of CRP respectively, compared with the first; P for trend < 0.001), restless sleep (ORs of 1.11, 1.15, and 1.37; P for trend = 0.002), and not being able to get going (ORs of 1.33, 1.40, and 1.60; P for trend = 0.007). The association with negative affect (“felt depressed”) was also statistically significant (P for trend = 0.03); but for other items relating to affect (sadness) and anhedonia were not (Tables 1 and 2). Additional adjustment for BMI partially attenuated estimates for restless sleep (ORs of 1.08, 1.11, and 1.30; P for trend = 0.002) and not being able to get going (ORs of 1.28, 1.31, and 1.45; P for trend = 0.02).

3.2. Association between C-reactive protein and depressive symptoms stratified by antidepressant use

For the one in ten participants who took antidepressants (10.6%), the association between CRP and all but the symptoms of restless sleep (model 1: $P = 0.03$; model 2: $P = 0.04$) and feeling depressed ($P = 0.02$) were not significant at conventional levels (model 1: Tables S1 and S2). In contrast, among study members not treated with antidepressants, there was an independent dose-response association for somatic symptoms (Table S3). The associations between CRP and restless sleep ($P = 0.16$) and not being able to get going ($P = 0.12$) were attenuated after adjustment for BMI, whereas the association for everything being an effort was not ($P < 0.001$).

There was a non-significant association between quartiles of CRP and psychological symptoms among those untreated with antidepressants (Table S3), and an inverse association between CRP and feeling depressed ($P = 0.02$). A significant interaction indicated the dose-response trend was stronger in those untreated than treated with antidepressants for the items relating to fatigue/low motivation – everything being an effort (P for a difference in trend = 0.02) and restless sleep (P for a difference in trend = 0.04, see Supplementary Fig. 1).

3.3. Sensitivity analyses

People with missing data had fewer symptoms of depression ($P < 0.001$), except restless sleep ($P = 0.09$); fewer reported baseline heart disease ($P = 0.005$), diabetes, rheumatoid arthritis and used antidepressants ($P < 0.001$); they had a lower body mass index and level of CRP ($P < 0.001$), more took beta blockers ($P = 0.03$), but no differences were found by age, sex, or the use of glucocorticoids ($P > 0.05$). The pattern of attenuation for our main results was replicated in models using the sum of the items assessing somatic (Tables S5) or psychological symptoms (Tables S6).
