by means of DP.

work in Section 5.

Many applications in biomedical imaging have a demand on automatic detection of lines, contours, or 089 boundaries of bones, organs, vessels, and cells. Aim is to support expert decisions in interactive applications or to include it as part of a processing pipeline for automatic image analysis. Biomedical images often suffer 090 from noisy data and fuzzy edges. Therefore, there is a need for robust methods for contour and line detec-091 tion. Dynamic programming is a popular technique that satisfies these requirements in many ways. This 092 work gives a brief overview over approaches and applications that utilize dynamic programming to solve 093 problems in the challenging field of biomedical imaging. 094

2. Motivation

In biomedical imaging many computer vision problems involve the detection of objects in pictures acquired through the various types of imaging techniques. A goal is to help physicians to automatically detect, track and analyze structures in biomedical images, to reduce the expert's workload, increase the productivity, and improve the accuracy of the diagnosis.

2.1. Application Overview

114 An example is the detection of the endocardial border of the 115 heart [6-9] and its movement [10-12] that gives valuable knowledge 116 (visually and quantitatively) about the heart function. Also artery and 117 vessel boundary detection, e.g. presented in [13-21] is of great inter-118 est, where the detection and evaluation of vessel boundaries and 119 vessel thickness (intima-media) is a marker to detect stenosis [16] 120 or helps in the diagnosis of atherosclerosis [15,19]. The work in [22] 121 proposes a technique to access the tree of fine vessels to determine 122 their progress and density. Beside investigations in the field of blood 123 supply, biomedical imaging is used to detect every kind of tumors, 124 organs, bones, and even cells. The works in [23-26] propose methods 125 to detect the ribs, spines and bones or specific parts of the spine, 126 while [27,28] focus on tumor and cancer detection. The segmenta-127 tion of microscopic cells includes approaches, where cell borders are 128 detected fully automatically, e.g. [29-31], or where a single cell is 129

segmented in a preselected ROI as done in [32,33]. Finally, there are 133 134 various applications that utilize DP in ophthalmology to examine parts of the eye [34-36] and in the field of mammography to detect 135 136 breast cancer [37-41].

2.2. Method Overview

140 Imaging modalities, e.g. MRI, ultrasound, X-ray, and microscopy, 141 not only differ from their fundamental physical idea, but also in 142 terms of usage (with contrast marker or without; invasive or not), 143 application (2D or 3D; still images or image sequences), and the 144 object or body part of interest. There exist a wide range of techniques 145 and applications to detect and analyze their content. Some appli-146 cations work totally automatically and some need user interaction. 147 Most of these approaches have to deal with difficulties like inhomo-148 geneities in the intensity of the targeted structures, strong noise or 149 other artifacts depending on the acquisition system.

150 In terms of the described problems and the demand on a specific 151 robustness. DP draws particular attention in biomedical imaging as 152 it always finds a global optimum and it outputs a connected path 153 despite of the presence of inhomogeneities and holes in the under-154 lying image features. The various studies, introduced in this section, 155 have in common to use DP in numerous ways.

156 Specific applications evoke specific questions. Most of the 157 reviewed works try to find the shortest path to detect a contour 158 or boundary in the image by minimizing some energy function by 159 means of dynamic programming. Finding a contour or line by DP, 160 for instance in ultrasonic data, demands techniques to properly 161 carve out edges in the presence of noise and artifacts. This requires 162 appropriate filtering and noise reduction such as proposed by Jia et 163 al. and Lee et al. [26,27] or the integration of high-level information 164 and prior knowledge to overcome uncertainties as approached by 165 Oost et al., Koh et al. and Ungru et al. [9,23,42].

166 Another application with specific requirements are circular 167 objects like cardiac and vascular borders in ultrasound and MRI 168 [10,11,13] or cells in microscopic images [29,31-33]. Also the 169 detection of the mammographic mass in a preselected ROI [37–41] 170 or the segmentation of the optic disk in retinal fundus images of 171 the eye as done in [36] aims to find circular structures by means 172 of DP. These applications arise the need of finding a circular path 173 with minimal cost: a circular shortest path (CSP). A CSP beside the optimality constraint demands the closedness of the contour as fur-174 175 ther restriction and is generally discussed by Sun and Pallottino [43] 176 and Appleton and Sun [44] and applied on biomedical images among 177 others in [8,10,11,13,24,29,33,37-39].

178 The evaluation of vessel border thickness [15,17-19], spine 179 boundaries [25,45], ribs [24], or retinal [35] and corneal layers [34] 180 necessitates to detect structures with two or more nearly parallel 181 contours. In general, the set of simultaneous paths with the lowest 182 cost in total is referred to as multiple shortest path (MSP). Neverthe-183 less, it is important to note that not all of the works above search for 184 an optimal solution for this problem.

185 A special type of shortest paths are active contours. Active con-186 tours are popular in biomedical imaging and can be implemented 187 with DP as shown by Amini et al. [2]. Active contours usually need 188 an initial contour, which is obtained by user interaction, random 189 generation, or a contour of a previous frame (in image sequences). 190 This initial contour is attracted iteratively through some forces to a 191 local minimum as originally proposed by Kass et al. [46]. While active 192 contours by Kass et al. are modeled as continuous curves, Amini et 193 al. introduce a discrete DP-based optimization approach, where con-194 tours are represented by some control points connected via splines. A 195 non-iterative approach of deformable contours is proposed in [10,11] 196 to attract a contour (represented by a few control points) to the left 197 ventricular border in MRI and track it over time. Other approaches 198 like [19,25] mainly use shape constraints instead of initial points to diminish the search space to arrange the contour points and attract 199 it to an object border. Deformation and tracking over time is also 200 examined in the approach of Pham and Doncescu [28]. 201

202 A further application of DP in biomedical imaging is proposed in [22], where a vascular tree is detected and represented as a 203 graph by means of a region growing technique based on DP. This 204 approach is the only reviewed approach that is not based on energy 205 minimization (Table 1). 206

3. Problems and Solutions

As discussed in Section 2 the introduced applications can be cat-212 egorized into a few problems. Most of them can be summarized as energy minimization tasks. A transfer of these problems into graphs allows us to simplify and generalize the description of the vari-215 ous reviewed approaches. An optimal path, hence the path with the lowest cost in a graph is also known as shortest path. This section gives a brief overview of shortest path problems solved by DP and introduces the most common methods.

3.1. Solving Shortest Path Problems by Dynamic Programming

A graph is a structure that contains nodes connected by edges. A 223 path in a graph is a connection of several nodes via edges. Each edge 224 can be associated with a specific weight, also known as cost. Then, 225 finding the shortest path in a graph means finding the path with the lowest cost sum of all edges in the path. According to Felzenszwalb and Zabih [47] there are two forms of shortest path problems. The 228 single-source type searches the shortest path from a source point s to 229 each of the remaining nodes while the *all-pairs* search tries to find 230 the shortest path between each possible pair of nodes in a graph. The 231 mentioned shortest path problems can be solved by generic shortest 232 path algorithms such as proposed by Dijkstra [48]. For an overview 233 we refer to [49]. 234

The single-source shortest path is the most frequently used type 235 and can be efficiently solved by DP. Dynamic programming sequen-236 tially solves the shortest path problem by splitting it into simpler 237 subproblems. Starting at node s, at each state i = 1, ..., n, the 238 algorithm evaluates the shortest path back to s. Because DP works 239 sequentially, it can only find shortest paths in a directed acyclic graph 240 (DAG) that is exemplary illustrated in Fig. 1. 241

A shortest path search is often utilized for discrete energy min-242 imization as shown in [5]. A common description of energy in 243 computer vision consists of two terms: energy based on observations 244 in some underlying data and energy of some prior, including con-245 straints of smoothness: 246

$$E = E_{data} + E_{prior}$$

Table 1 Efficiency of the main methods.

Method		25
SP	$\mathcal{O}(k^2n)$	25
Matrix-based approaches		25
– SP	O(kmn)	25
– MSP	$\mathcal{O}(k^p m^p n)$	25
– CSP – MSA	$O(km^2n)$	25
– CSP – IPA	$\mathcal{O}(km\hat{n}), \hat{n} > n$	26
– CSP – MBTA	O(kmn)	20
Active contours		26
– ordinary approach	$O(k^3n)$	26
– circular contours, MSA	$\mathcal{O}(k^4n)$	26
 – circular contours, randomly fixed neighbors 	$O(k^3n)$	26
