ABSTRACT

The effective management of pain is a longstanding public health concern. Morphine-like opioids have long been front-line analgesics, but produce undesirable side effects that can limit their application. Slow progress in the introduction of novel improved medications for pain management over the last 5 decades has prompted a call for innovative translational research, including new preclinical assays. Most current in vivo procedures (eg, tail flick, hot plate, warm water tail withdrawal) assay the effects of nociceptive stimuli on simple spinal reflexes or unconditioned behavioral reactions. However, clinical treatment goals may include the restoration of previous behavioral activities, which can be limited by medication-related side effects that are not measured in such procedures. The present studies describe an apparatus and procedure to study the disruptive effects of nociceptive stimuli on voluntary behavior in nonhuman primates, and the ability of drugs to restore such behavior, through their analgesic actions. Squirrel monkeys were trained to pull a cylindrical thermode for access to a highly palatable food. Next, sessions were conducted in which the temperature of the thermode was increased stepwise until responding stopped, permitting the determination of stable nociceptive thresholds. Tests revealed that several opioid analgesics, but not d-amphetamine or Δ^9 -THC, produced dose-related increases in threshold that were antagonist sensitive and efficacy dependent, consistent with their effects using traditional measures of antinociception. Unlike traditional reflex-based measures, however, the results also permitted the concurrent evaluation of response disruption, providing an index with which to characterize the behavioral selectivity of antinociceptive drugs.

1. Introduction

The effective management of pain remains an important public health concern. Although morphine-like opioids have long been front-line analgesics for most painful conditions, their clinical utility is restricted by well-recognized liability for side effects, including dependency/addiction, respiratory depression, and sedation [3]. Despite the clear need for improved analgesics, progress in the discovery and development of novel candidate medications for pain management over the last 5 decades has been slow. This has provoked well-publicized concern [7,23], leading to the suggestion that traditional nociception assays might be inadequate for the task of identifying novel candidate medications for pain management, and, correspondingly, that new animal models are needed for translational pain research [27,29,32,33,44].

Currently, analgesiometry in laboratory animals primarily uses thermal, electrical, chemical, and mechanical nociception to assay the antinociceptive effects of candidate analgesics [28]. Most commonly used approaches (eg, tail flick, hot plate, acid-induced writhing, warm water tail withdrawal), use simple spinal reflexes or unconditioned behavioral reactions to nociceptive stimuli. These approaches present both conceptual and experimental limitations. From a conceptual standpoint, simple reflex measures fail to adequately capture any involvement of supraspinal areas of the central nervous system in pain-stimulated responses [5,8,31,44]. Therefore, preclinical animal models of nociception are needed to assay behavioral responses that clearly involve higher-order cortical function. From an experimental standpoint, conventional assays usually rely on a decrease in response (eg, longer latency to tail flick, decreased writhing, etc). Therefore, it is often difficult to distinguish the role of nonspecific depression of behavior in candidate analgesics. For example, morphine has sedative effects over the same range of doses that increase the latency to tail flick, and the interaction of these effects is uncertain.

83 One way to address the above issues is to establish an index of
 84 antinociception that relies on the restoration, rather than suppres-
 85 sion, of a response under otherwise nociceptive conditions.
 86 Operant-based tasks, unlike assays of reflexive or unconditioned
 87 behavioral responses, involve the subject engaging in a volitional
 88 response that necessarily involves centrally mediated processes.
 89 Thus, such tasks provide an important alternative approach for
 90 the evaluation of candidate analgesics. The utility of an operant-
 91 based approach has received some attention [27,29,33,44]; how-
 92 ever, few studies have been conducted to examine the effects of
 93 antinociceptive drugs under operant contingencies. Notable excep-
 94 tions, however, include the operant orofacial apparatus [2,35,36,40]
 95 and operant escape procedure [6,43,49].

96 The present report describes an apparatus and operant proced-
 97 ure to examine both the disruptive effects of nociceptive stimuli
 98 on voluntary responses in nonhuman primates and behaviorally
 99 restorative effects of analgesics. Squirrel monkeys were trained
 100 to respond (by pulling down a cylindrical thermode) for a palatable
 101 food reinforcer. Next, experiments were conducted in which the
 102 temperature of the thermode was increased stepwise until
 103 responding stopped. This permitted the determination of nocicep-
 104 tive thresholds, which proved to be highly stable over time and
 105 sensitive to varying parameters of the response requirement.
 106 Finally, tests with several types of drugs purported to produce
 107 analgesia were conducted to assess their antinociceptive effects
 108 under these conditions.

109 2. Methods

110 2.1. Subjects

111 Four adult male squirrel monkeys (*Saimiri sciureus*) were indi-
 112 vidualy housed in a temperature- and humidity-controlled vivari-
 113 um with a 12-hour light/dark cycle (7 AM–7 PM). Subjects had
 114 unlimited access to water in the home cage and were maintained
 115 at approximate free-feeding weights by post-session access to a
 116 nutritionally balanced diet of high-protein banana-flavored bis-
 117 cuits (Purina Monkey Chow, St. Louis, MO). In addition, fresh fruit
 118 and environmental enrichment were provided daily. Experimental
 119 sessions were conducted 5 days per week (Monday–Friday). The
 120 experimental protocol for the present studies was approved by
 121 the Institutional Animal Care and Use Committee at McLean Hospi-
 122 tal. Subjects were maintained in a vivarium licensed by the U.S.
 123 Department of Agriculture and in accordance with the Guidelines
 124 for the Care and Use of Mammals in Neuroscience and Behavioral
 125 Research [34].

126 2.2. Apparatus

127 Fig. 1 shows a drawing of the operant nociception chamber. A
 128 custom-built Plexiglas chair measuring 25 cm × 25 cm × 40 cm
 129 was housed in a 50 cm × 50 cm × 75 cm sound- and light-attenu-
 130 ating enclosure. A digital video camera was mounted in the inside
 131 upper-right corner of the enclosure for real-time session monitor-
 132 ing and an infusion pump (PHM- 100-10; Med Associates, St.
 133 Albans, VT) was mounted outside the left wall of the enclosure
 134 for the delivery of liquid reinforcement. Briefly, each operation of
 135 the pump delivered 0.15 mL of 30% sweetened condensed milk
 136 (70% water) via Tygon Microbore tubing (0.40 inner diameter,
 137 0.70 outer diameter; Saint-Gobain Performance Plastics, Paris,
 138 France) into an easily accessible shallow well (2.5 cm in diameter)
 139 of a custom-designed Plexiglas fluid dispenser (5 × 3.5 × 1.27 cm)
 140 mounted to the inside front wall of the chair. Previous studies in
 141 our laboratory have found that a small volume (0.15 mL) of this
 142 liquid serves as a powerful reinforcer for squirrel monkeys that is
 143 very resistant to satiation even under free-feeding conditions

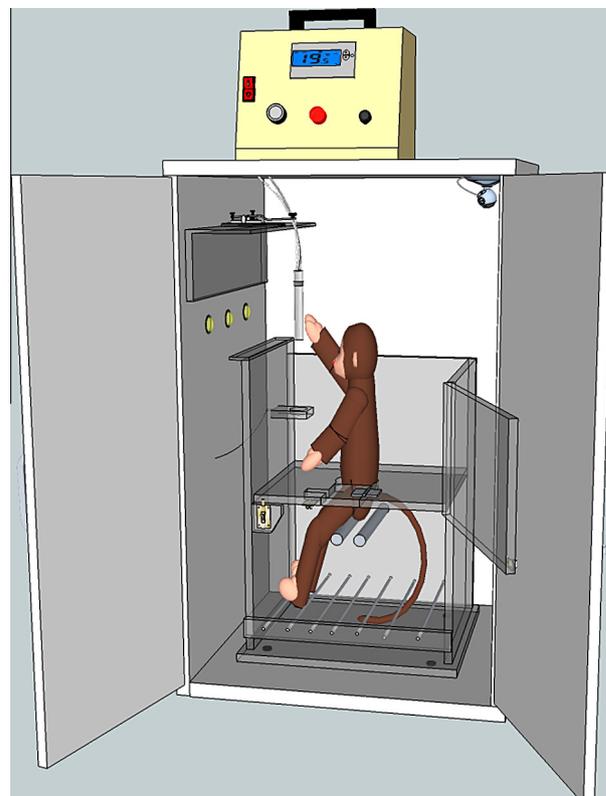

Fig. 1. Schematic representation of the operant nociception chamber (see Apparatus section for additional details).

144 [19]. Three horizontally arrayed white stimulus lights (2.5 cm in
 145 diameter) were mounted 50 cm above the enclosure floor, spaced
 146 10 cm apart and centered above the fluid dispenser. A telegraph
 147 key was secured to a shelf 15 cm above the stimulus lights, and a
 148 custom-built stainless steel 500 w/120 v thermode (1.27 cm in
 149 diameter; 15.24 cm in length) with fiberglass leads hung from
 150 the telegraph key button via a 5-cm chain. A downward pull of
 151 the thermode closed the telegraph key circuit, making an electrical
 152 contact that could serve as a response. A temperature sensor (TBC-
 153 72.OG, Convectronics, Haverhill, MA) was attached to the upper
 154 end of the thermode, which also was attached via the fiberglass
 155 leads to a 120 v, 15 amp temperature control unit (Control Console
 156 006-12015, Convectronics, Haverhill, MA). This unit served as a
 157 thermostat and controlled the temperature of the thermode with a
 158 resolution of ±1°C. All temperature settings and adjustments were
 159 made by the experimenter. Other experimental events (ie,
 160 pull detection, operation of stimulus lights, milk delivery) and data
 161 collection were controlled by Med Associates (St. Albans, VT) inter-
 162 facing equipment and operating software.

163 2.3. Procedure

164 2.3.1. Pull training

165 During experimental sessions, subjects were seated in the chair.
 166 Each subject was trained with response shaping [4], first to drink
 167 from the milk well and then to pull the thermode downward to
 168 close the telegraph key. Trials began with illumination of the left
 169 and right stimulus lights. Thermode pulls with a force of at least
 170 2.78 N closed the telegraph key circuit and were recorded as
 171 responses. During initial training, each circuit closure immediately
 172 extinguished the left and right stimulus light and illuminated the
 173 center stimulus light for 2 seconds, delivered 0.15 mL of milk into
 174 the well, and was followed by a 10-second intertrial interval (ITI)
