Bezafibrate

ABSTRACT

Introduction: Carnitine palmitoyltransferase II (CPT II) deficiency is an inherited disorder involving β-oxidation of long-chain fatty acids (FAO), which leads to rhabdomyolysis and subsequent acute renal failure. The detailed mechanisms of disease pathogenesis remain unknown; however, the availability of relevant human cell types for investigation, such as skeletal muscle cells, is limited, and the development of novel disease models is required.

Methods: We generated human induced pluripotent stem cells (hiPSCs) from skin fibroblasts of a Japanese patient with CPT II deficiency. Mature myocytes were differentiated from the patient-derived hiPSCs by introducing myogenic differentiation 1 (*MYOD1*), the master transcriptional regulator of myocyte differentiation. Using an *in vitro* acylcarnitine profiling assay, we investigated the effects of a hypolipidemic drug, bezafibrate, and heat stress on mitochondrial FAO in CPT II-deficient myocytes and controls.

Results: CPT II-deficient myocytes accumulated more palmitoylcarnitine (C16) than did control myocytes. Heat stress, induced by incubation at 38 °C, leads to a robust increase of C16 in CPT II-deficient myocytes, but not in controls. Bezafibrate reduced the amount of C16 in control and CPT II-deficient myocytes.

Discussion: In this study, we induced differentiation of CPT II-deficient hiPSCs into mature myocytes in a highly efficient and reproducible manner and recapitulated some aspects of the disease phenotypes of CPT II deficiency in the myocyte disease models. This approach addresses the challenges of modeling the abnormality of FAO in CPT II deficiency using iPSC technology and has the potential to revolutionize translational research in this field.

1. Introduction

β-Oxidation of long-chain fatty acids (LCFA) occurs in the mitochondria with the activity of carnitine palmitoyltransferase II (CPT II; EC2.3.1.21), carnitine-acylcarnitine translocase (CACT), CPT I, and acyl-coenzyme A (CoA) synthetase. These enzymes mediate LCFA transport from the cytosol into the mitochondria. In response to conditions with a high-energy demand, such as intensive exercise, severe infection, and fasting, LCFA transfer is promptly activated [1–4]. *CPT2* maps to chromosome 1p32, spans 20 kb, contains five exons, and encodes the CPT II enzyme. Defects in CPT II enzymatic activity are classified into three clinical categories in humans: lethal neonatal (MIM #608836), severe infantile (MIM #600649), and mild adult-onset (MIM #255110) types. Due to the low enzymatic activity of CPT II, the neonatal and infantile forms result in liver failure, hypoketotic hypoglycemia, and cardiomegaly. The neonatal form causes death within several months. The infantile form has been implicated in cases of sudden infant death syndrome. On the other hand, the adult-onset type

manifests as recurrent myalgia (muscle pain), rhabdomyolysis, and myoglobinuria, which can cause acute renal failure. CPT II deficiency is generally considered an autosomal recessive disease; however, many cases of symptomatic carriers have been reported [5]. Individuals who carry a *CPT2* mutation [6–9] may develop the clinical features of CPT II deficiency when treated with medications that affect the activity of the remaining wild-type CPT II enzyme.

In this study, we successfully derived human induced pluripotent stem cells (hiPSCs) from a patient with CPT II deficiency, differentiated them into a mature myocyte lineage within 2 weeks in a highly efficient and reproducible manner, and recapitulated some of the disease phenotypes associated with CPT II deficiency. We discuss the opportunities to use iPSC technology for modeling defects in FAO and for evaluating therapeutic regimens for CPT II deficiency.

2. Patient and methods

2.1. Patient

The subject of the current study was a 24-year-old Japanese man whose genetic and clinical presentation has already been described [10]. The patient suffered from acute renal failure induced by rhabdomyolysis and was diagnosed as having adult-onset CPT II deficiency. Skin biopsy samples were obtained from the patient with his written informed consent. This study was approved by the Ethics Committee on hereditary disease, Research of the Graduate School of Medical Sciences, Fukuoka University, and by the Ethics Committee of Kyoto University. The dermal fibroblasts were expanded from skin biopsy explants in Dulbecco's modified Eagle's medium (DMEM; Nacalai Tesque, Kyoto, Japan) supplemented with 10% fetal bovine serum (Japan Bioserum, Hiroshima, Japan). Control iPSCs (201B7) were previously established from the facial dermis of a 36-year-old Caucasian woman at the Center for iPS Cell Research and Application (CiRA), Kyoto University [11].

2.2. Methods

2.2.1. Generation of hiPSCs from the patient

CPT II deficiency-specific hiPSCs were derived from the patient by transducing the four reprogramming factors (OCT4, SOX2, KLF4, and c-MYC) or three factors (excluding c-MYC) into skin fibroblasts with retrovirus vectors as previously described [11,12]. In brief, fibroblasts derived from the CPT II-deficient patient were maintained and expanded in DMEM containing 10% fetal bovine serum. The patient fibroblasts were seeded in 6-well plates at 1.0×10^5 -cells/well. The next day, the cells were infected with Slc7al lentiviruses with 4 μg/mL polybrene (Nacalai Tesque). Fibroblasts expressing the mouse Slc7al were seeded in 6-well plates at 1.0×10^5 cells/well 1 day before transduction. Equal amounts of four retrovirus-containing supernatants were mixed and supplemented with 4 μg/mL polybrene. Six days after transduction, the fibroblasts were replated onto mitomycin C-treated SNL feeder cells. Thirty days after transduction, iPSC colonies were selected for expansion.

2.2.2. Cell culture

CPT II-deficient hiPSCs were cultured as previously described [11]. The hiPSCs were grown on mitomycin C-treated SNL feeder cells in Primate ES medium (ReproCELL, Kanagawa, Japan) supplemented with 500 U/mL penicillin/streptomycin (Invitrogen, Carlsbad, CA) and 4 ng/mL recombinant human basic fibroblast growth factor (bFGF, Wako, Osaka, Japan). For routine passaging, hiPSC colonies were dissociated by an enzymatic method with CTK dissociation solution consisting of 0.25% trypsin (Invitrogen), 0.1% collagenase IV (Invitrogen), 20% knockout serum replacement (KSR, Invitrogen), and 1 mM $CaCl_2$ in PBS (Nacalai Tesque) and split at a ratio between 1:3 and 1:6.

2.2.3. Embryoid body (EB) formation

For EB formation, a 10-cm plate containing hiPSCs was rinsed with PBS and treated with 1 mg/mL type IV collagenase (Invitrogen) in DMEM for 10 min at 37 °C. The collagenase was rinsed away with PBS and replaced with undifferentiation medium. The cells were then scraped off with a cell scraper (IWAKI, Tokyo, Japan), dissociated by pipetting, and distributed into a low attachment 6-well plate (Corning, Tokyo, Japan) containing knockout-DMEM (Invitrogen) supplemented with 20% KSR, 0.1 mM nonessential amino acids (Invitrogen), 2 mM glutamine (Invitrogen), 500 U/mL penicillin/streptomycin, and 0.55 mM 2-mercaptoethanol (Invitrogen). After 8 days as a floating culture, the EBs were transferred to gelatin-coated plates and cultured in the same medium for another 8 days.

2.2.4. Teratoma formation

The undifferentiated iPSCs were harvested using CTK dissociation solution, collected, and centrifuged, and the pellets were resuspended in DMEM/F12 (Invitrogen). A quarter of the iPSCs from a confluent 10-cm plate was injected into the testes of a non-obese diabetic/severe combined immunodeficient (NOD-SCID mouse, CLEA, Tokyo, Japan). Nine to 12 weeks after injection, the tumors were dissected and fixed with PBS containing 4% paraformaldehyde (PFA). Paraffin-embedded tissues were sectioned and stained with hematoxylin and eosin.

2.2.5. Mutational analysis of the CPT2 in patient-derived iPSCs

Overlapping PCR primers that targeted CPT2 exons were designed to cover the entire coding region (Table 1; GenBank accession No. M58581). The PCR protocol was as follows: 30 cycles of 1 min at 94 °C for denaturation, 1 min at 60 °C for annealing, and 1 min at 72 °C for extension, followed by 1 cycle of 10 min at 60 °C for completion. Each PCR product was sequenced on an automated DNA sequencer (ABI 3100 Genetic Analyzer; Applied Biosystems Hitachi, Tokyo, Japan) by using the BigDye Terminator v3.1 cycle-sequencing kit (Applied Biosystems, Foster City, CA) and the sequencing primers listed in Table 1.

2.2.6. Induction of hiPSCs into skeletal muscle cells

We used our previously reported method in which *MYOD1* overexpression in undifferentiated hiPSCs efficiently and reproducibly induces differentiation into mature skeletal muscle cells within 10 days [13]. Briefly, we transduced a self-contained Tet-inducible MYOD1 expressing *piggyBac* vector (Tet-MYOD1 vector) and transposase into CPT II-deficient iPSCs by lipofection. This system allows the indirect monitoring of induced *MYOD1* expression in response to doxycycline (Dox) by co-expression of a red fluorescent protein (mCherry). It was also reported that low glucose culture conditions purified the cardiomyocytes from mouse and human iPSC differentiation cultures by selecting only cardiomyocytes, based on the findings of the substantial biochemical differences in glucose and lactate metabolism between cardiomyocytes and undifferentiated iPSCs [14]. We used a similar strategy to increase the purity of generated myocytes and cultured the hiPSC-derived differentiated cells with low glucose media (1.0 g/L) for an additional day after 10 days of myocyte induction by *MYOD1* overexpression. The low-glucose medium was composed of MEM (Sigma, St. Louis, MO) containing 0.4% bovine serum albumin (Sigma), 0.4 mM L-carnitine (Sigma), 0.2 mM unlabeled palmitic acid (Nacalai Tesque), and 500 U/mL penicillin/streptomycin. For
