HBV cccDNA
Lentiviral vector
RNA-directed DNA methylation
Short hairpin RNA

ABSTRACT

Small interfering RNAs not only modulate gene expression at a post-transcriptional level, but also induce transcriptional gene silencing by RNA interference-mediated heterochromatin formation and RNA-directed DNA methylation (RdDM). However, although established in plants, there have been controversies whether RdDM operates in mammals. Hepatitis B virus (HBV) covalently closed circular DNA (cccDNA) serves as a template for viral RNA transcription, and transcriptional activity of HBV cccDNA is regulated by methylation in patients with chronic HBV infection. In this study, we stably expressed short hairpin RNA (shRNA) against HBV in human hepatoma cells to determine whether shRNA induces methylation of HBV cccDNA. HepAD38 cells which permit replication of HBV under control of tetracycline-responsive promoter were transduced with lentiviral vectors which encode sh-1580, a shRNA against the hepatitis B viral protein HBx. Bisulfite sequencing PCR analysis revealed that sh-1580 induced CpG methylations at a higher rate compared to control (31.3% vs. 12.8%, $p < 0.05$). The sh-1580-induced CpG methylation was localized near the target sequence of sh-1580 in more than a half of the clones. Methylation-induced transcriptional suppression was confirmed by *in vitro* transcription assay. These results confirm the feasibility of RdDM of HBV cccDNA in human cells. Lentiviral vector-mediated transfer of shRNA may be used as a tool for novel transcriptional modulation by epigenetic modification of HBV cccDNA.

1. Introduction

The RNA interference (RNAi) is a double-stranded RNA-dependent mechanism which regulates eukaryotic gene expression in a wide variety of organisms [1]. Small interfering RNAs (siRNAs), a representative effector of RNAi, control gene expression at a post-transcriptional level by forming RNA-induced silencing complexes, which in turn recognize target RNA sequence and either induce mRNA degradation or translational repression [2,3]. In addition to post-transcriptional gene silencing (PTGS), it has become apparent over the last decade that siRNA also induces transcriptional gene silencing (TGS) by RNAi-mediated heterochromatin formation and RNA-directed DNA methylation (RdDM) [4]. Whereas siRNA-induced heterochromatin formation has been characterized in animal cells [5], there have been conflicting results regarding whether RdDM operates in mammals [4].

Human DNA viruses are cytosine-methylated in host cells, especially during latency [6], and methylation of viral genome may be an innate antiviral defense. However, the mechanisms of viral DNA methylation during natural human infection have not been fully elucidated. Interestingly, several recent reports suggest that small RNAs (siRNAs and microRNAs) may induce methylation of integrated or episomal viral DNA [7,8]. Hepatitis B virus (HBV) is a partially double-stranded circular DNA virus which is one of the most important causes of liver cirrhosis and hepatocellular carcinoma worldwide. After entering hepatocytes, the viral genome becomes fully double-stranded covalently closed circular DNA (HBV cccDNA) and functions as a episomal template for viral transcription [9]. HBV cccDNA is methylated in the human liver [10,11], and we found that methylation of cccDNA regulates the transcriptional activity of cccDNA in chronic HBV infection [12]. DNMT3 may be responsible for the methylation of HBV cccDNA [13], but the exact mechanisms are still elusive.

Abbreviations: cccDNA, covalently closed circular DNA; HBV, hepatitis B virus; siRNA, small interfering RNA; shRNA, short hairpin RNA; PTGS, post-transcriptional gene silencing; RdDM, RNA dependent DNA methylation; RNAi, RNA interference; TGS, transcriptional gene silencing.

In this work, we showed that lentiviral vector-mediated transfer of short hairpin RNA (shRNA) against HBV is capable of inducing methylation of HBV cccDNA and transcriptional suppression in human hepatoma cells.

2. Materials and methods

2.1. Cells and reagents

HepAD38 cells which produce HBV under the control of tetracycline-responsive CMV-IE promoter were a generous gift from professor C. Seeger (Fox Chase Cancer Center, PA) [14]. 293FT cells were purchased from Invitrogen (Carlsbad, CA). Polybrene (hexadimethrine bromide) and tetracycline were purchased from Sigma–Aldrich Chemical Co. (St. Louis, MI).

2.2. Lentivirus-mediated transfer of shRNA against HBV to HBV-replicating cells

A shRNA sequence against HBV X gene (sh-1580) was cloned into HIV-based plasmid to generate a 3rd generation lentiviral vector as described previously [15,16]. Briefly, a target sequence in the HBX region of HBV genome (nt 1580–1604, TGCACTTCGCTTCACCTCTGCACGT) [17] was assembled in the downstream of the human Pol III U6 promoter by PCR using pTZ U6 + 1 plasmid as a template and the following 3′ primer [15,16,18]: 5′-GGAAGATCTAGAAAAAATGCACTTCGCTTCACCTCTGCACGTT*CTCTTGA*AACGTGCAGAGGTGAAGCGAAGTGCACCGGTGTTTCGTCCTTTCCACAAG-3′. For a negative control, a scrambled shRNA was prepared with the following 3′ primer [19]: 5′-GGAAGATCTAGAAAAAAGCACCTAT AACAACGGTAG*CTACACAAA*CTACCGTTGTTATAGGTGCCGGTGTTTCG TCCTTTCCACAAG-3′. Underlined nucleotides indicate HBV target (sense) and scrambled RNA, respectively, and italicized nucleotides indicate loop sequences of shRNA. Amplified shRNA expression cassettes were cloned into a lentiviral backbone plasmid (pHIV7-GFP PL) as described [15]. The recombinant plasmid was cotransfected with core packaging plasmids (pMDLg/pRRE and pRSV-Rev) and envelope plasmid (pMD2.VSVG) to a packaging 293FT cell line. The medium was replaced with a fresh medium 16 h after transfection, and the supernatant was collected after 24 h of further incubation. Real-time quantitative RT-PCR was performed to determine the lentiviral titers as described [20].

2.3. Transduction of lentiviral vectors in HepAD38 cells

HepAD38 cells were maintained as described [14]. On the day of transduction, cells were plated at a density of 5×10^5 cells in 60-mm cell culture dishes and 1×10^9 particles of lentivirus were added to the medium along with polybrene at final concentration of 4 μg/ml. From the 4th day following transduction, the cells were maintained without tetracycline for five days to induce replication of HBV, and then tetracycline was replenished again in the culture medium until harvest. Cells were harvested on 14th days after transduction for the evaluation of HBV replication and HBV cccDNA methylation.

2.4. Bisulfite sequencing PCR analysis of HBV cccDNA

HBV cccDNA was extracted by using a modified Hirt extraction procedure, followed by digestion with Plasmid-safe DNase (Epicentre, Madison, WI) as described [12]. One-hundred nanograms of the enzyme-treated DNA samples were subject to bisulfite modification by using Imprint DNA Modification Kit as recommended by the manufacturer (two-step modification procedure, Sigma Cat. No MOD50). The modified DNA was PCR amplified using the following primer pairs which were designed by MethPrimers software in order to amplify the bisulfite-modified HBX gene region (nt 1327 – 1670): F, 5′-GGGATTGATAATTTTGTTGTTTTTTT-3′; R, 5′-TCCAAAAATCCTCTTATATAAAACCTTAA-3′ [12,21]. The amplicons were cloned into pDrive TA cloning vector (Qiagen) and sequenced. Modified DNA sequences were analyzed by the software BiQ Analyser as recommended [22].

2.5. Southern and Northern blotting

Cytoplasmic HBV DNA and RNA were isolated from the harvested HepAD38 cells as described [12]. Southern blotting was performed using the digoxigenin-labeled single-strand DNA probe as described [12]. HBV RNA was subject to Northern blotting as described [23].

2.6. In vitro transcription assay

Transcriptional activity of HBV cccDNA was assessed by *in vitro* transcription assay as described [12]. Briefly, 5×10^5 copies of HBV cccDNA from lentivirus-treated HepAD38 cells were incubated with the following reaction mixture: 12 mM HEPES (pH 7.6), 12% (v/v) glycerol, 0.12 mM EDTA, 60 mM KCl, 7.5 mM $MgCl_2$, 500 μM each of ATP, CTP, GTP, and UTP, 7 mM creatine phosphate, 0.3 mM DTT, 0.3 mM PMSF, 10U RNAsin (Promega, Madison, WI) and 7 mg/ml of Huh7 cell nuclear extract. Alpha-amanitin was used to exclude the possibility of contamination with pre-existing HBV RNA. The reaction mixture with HBV cccDNA was incubated at 30 °C for 45 min, and then treated with DNase I for 30 min at 37 °C to remove template cccDNAs. The RNA was reverse transcribed using random hexamers, and PCR amplified by using the following primer pairs: forward, 5′-CACCTCTGCCTAATCATC-3′; reverse, 5′-GGAAAGAAGTCAGAAGGCAA-3′.

3. Results and discussion

3.1. shRNA against HBV induces methylation of HBV cccDNA in HepAD38 cells

Whereas the effect of the exogenous siRNA lasts for <1 week in rapidly dividing cell lines [24], our previous study showed that suppressive effect of HBV-specific shRNA can be maintained up to 4 weeks after lentiviral transduction [16]. Repeated experiments confirmed that suppressive effect of shRNA against HBX region (sh-1580) last at least 2 weeks after lentiviral transduction (Fig. 1).

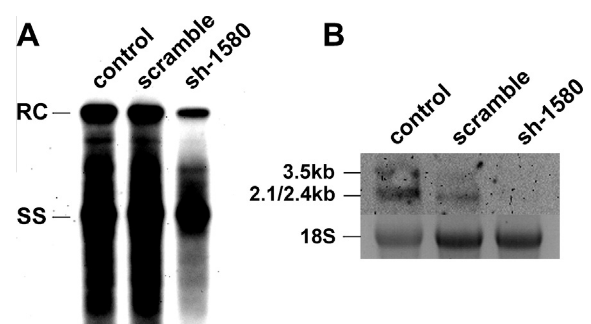

Fig. 1. Suppressive effect of lentivirus-delivered shRNA on HBV replication. HepAD38 cells were transduced with lentiviral vectors which encode scrambled RNA (scramble) or shRNA against HBV (sh-1580). HBV replicative intermediates and mRNA were extracted from the cells and analyzed by Southern (A) and Northern (B) blotting, respectively. The positions of HBV pregenomic RNA (pgRNA) (3.5 kb) and preS/S RNA (2.4/2.1 kb) are indicated, and 18S ribosomal RNA was shown as the loading control. RC, relaxed circular DNA; SS, single-strand DNA; control, HepAD 38 cells without lentiviral transduction.
