ABSTRACT

Filopodia are sensors on both excitable and non-excitable cells. The sensing function is well documented in neurons and blood vessels of adult animals and is obvious during dorsal closure in embryonic development. Nerve cells extend neurites in a bidirectional fashion with growth cones at the tips where filopodia are concentrated. Their sensing of environmental cues underpins the axon's ability to "guide," bypassing non-target cells and moving toward the target to be innervated. This review focuses on the role of filopodia structure and dynamics in the detection of environmental cues, including both the extracellular matrix (ECM) and the surfaces of neighboring cells. Other protrusions including the stereocilia of the inner ear and epididymus, the invertebrate Type I mechanosensors, and the elongated processes connecting osteocytes, share certain principles of organization with the filopodia. Actin bundles, which may be inside or outside of the excitable cell, function to transduce stress from physical perturbations into ion signals. There are different ways of detecting such perturbations. Osteocyte processes contain an actin core and are physically anchored on an extracellular structure by integrins. Some Type I mechanosensors have bridge proteins that anchor microtubules to the membrane, but bundles of actin in accessory cells exert stress on this complex. Hair cells of the inner ear rely on attachments between the actin-based protrusions to activate ion channels, which then transduce signals to afferent neurons. In adherent filopodia, the focal contacts (FCs) integrated with ECM proteins through integrins may regulate integrin-coupled ion channels to achieve signal transduction. Issues that are not understood include the role of Ca^{2+} influx in filopodia dynamics and how integrins coordinate or gate signals arising from perturbation of channels by environmental cues.

Q6 1. Introduction

74 1.1. Protrusions and their properties

75 1.1.1. Protrusion classes

76 Cell protrusions are essential for motility, chemotaxis, and haptotaxis.
 77 Three protrusion archetypes are commonly recognized in cultured mam-
 78 malian cells. They differ in size and shape as well as in their physiological
 79 characteristics. Pseudopodia-like protrusions called lamellipodia are
 80 found at the leading edge of the cell and typically form a shallow arc at
 81 the most distant point from the cell center. In the motile cell, the
 82 lamellipodium is extended in the direction of travel. However, the
 83 movement itself proceeds by periodic protrusion and retraction, with
 84 the degree of retraction typically less than that of the protrusion [1].
 85 The edge of the cell, both at the lamellipodium and elsewhere, is charac-
 86 terized by dynamic ruffling activity. In ruffles, the actin filaments extend
 87 upward from the edge, i.e., perpendicular to the surface of the culture
 88 dish. Previous studies reported that lamellipodia and ruffles are altered
 89 in oncogenically transformed cells. Some investigators found that
 90 lamellipodia were formed in multiple quarters of the cell [2], and ruffling
 91 was generally enhanced in transformed cells [3,4]. A third protrusion arch-
 92 etype is the filopodium, a small, tapering structure with a sharp tip at
 93 the distal end. In metazoan cells, filopodia are sensors of the microenvi-
 94 ronment [5]. In the growth cone, a single filopodium making contact
 95 with a more adhesive substrate is able to set the direction of neurite ex-
 96 tension [6].

97 Since the above features are loosely defined, a single physiological
 98 protrusion is inevitably called different names by different investigators.
 99 In addition, different protrusions can be named the same thing in differ-
 100 ent laboratories. The problems posed by this semantic “free-for-all” be-
 101 come apparent when a fourth type of protrusion, the neurite, is
 102 considered. Neurites are often defined as protrusions whose length ex-
 103 ceeds twice the cell diameter. If this is taken as a physiological defini-
 104 tion, however, it gives rise to the *reductio ad absurdum* argument that
 105 a short precursor of the neurite cannot exist. The problems have been
 106 addressed more recently by giving features a definition based on quan-
 107 titative data. A method of sampling shape geometries in 3D was used to
 108 generate values for many variables including: a) measures of positive
 109 curvature, e.g. bending energy, b) measures of contour length in posi-
 110 tive and negative curvature, c) relationship of the contour to derived
 111 model figures, e.g. ellipse of concentration or a figure formed by
 112 connecting the nearest or farthest points of the contour (“shrink-
 113 wrap”), d) dimensions of each protrusion modeled as a triangle, and
 114 e) measures of the area included in or excluded from the model figures.
 115 The methods are described in previous publications [7–12].

116 There are methods of aggregating variables that do not rely upon any
 117 prior assumptions about the statistical distribution of the data. When
 118 data are collected about cell geometry and then evaluated by factor
 119 analysis, one obtains unbiased classes or features. The resulting vari-
 120 ables, latent factors, corresponded to different cell features including
 121 four protrusions. The relationship between factors' values and protru-
 122 sion characteristics is defined in Table 1. The smallest features, indexed
 123 by factor #4, corresponded to filopodia [8,13]. Although the ruffle is re-
 124 cognizable by eye in most cultured cells, this feature was not extracted
 125 from the primary data by unbiased classification. When correlations
 126 among the features, including ruffles, were analyzed, the results showed
 127 that ruffles could originate from multiple factors. Factor #4 values were
 128 inversely correlated to ruffling, whereas ruffling tended to increase with
 129 increases in factor #5 [13]. By definition, variables generated by factor

analysis are independent, and indeed, the data show that the formation
 and turnover of each of the protrusion types are distinct, suggesting that
 they are irreducible features [9,10,12,14]. Since the ruffle lacked such in-
 dependence, it would not have been extracted as a latent factor.

How do the mathematical factors correspond to features known
 from conventional morphological studies, such as the above arche-
 types? Here, we reveal distinctions among the unbiased classes by illus-
 trating cells in which one protrusion class is high and the others low, as
 shown in Fig. 1. To simplify the presentation, only the three classes that
 account for a high proportion of overall variance in the data are illustrat-
 ed. Factor #4 clearly corresponds to filopodia. The classification also
 yielded a strap-shaped or triangular-shaped feature with bulkier dimen-
 sions. This feature, factor #7, was identified as a nascent neurite
 [12,14]. The remaining factors, #5 and #16, are less well understood.
 Factor #5 values depend on mass distribution around the cell center.
 Despite their distinct identities, there is little doubt that both #5 and
 #7 features would be called lamellipodia on a descriptive basis. The
 physiological distinction is important, however. A neurite is formed by
 the cell without cycles of protrusion and retraction and rarely involves
 locomotion of the whole cell. In contrast, the lamellipodium is associat-
 ed with recurrent extensions and retractions of the leading edge, and it
 facilitates locomotion of the whole cell.

1.1.2. Subjectively defined classes

Both lamellipodia and filopodia depend on the polymerization and
 depolymerization of actin filaments. The filaments in filopodia intersect
 with the membrane at angles greater than 60° and are formed into a
 paracrystalline array by the actin-binding protein, fascin [15,16]. In con-
 trast, filaments in lamellipodia are thought to intersect the plasma
 membrane at a mean angle of 50° [17], although angles up to 90° have
 been reported [18]. In dynamic studies, the two types of protrusions
 are distinguished by the speed of process formation and retraction. The
 larger protrusions move outward by 30–100 nm/s (1.8–6.0 μm/min)
 and the smaller by 100–200 nm/s. In the nerve growth cone, the
 filopodia may protrude at 500–700 nm/min (~0.1 μm/s). Speeds ranging
 as high as 3 μm/min or more have been observed, with most of
 the variation caused by differences in the rates of actin filament assem-
 bly [19,20]. The protrusions respond differently to osmolarity, as
 lamellipodia expand faster in hypotonic and filopodia faster in hypertonic
 media [21] (reviewed in [22]). Lamellipodia expansion occurs some
 20 s before maximal actin subunit addition [23], which supports previ-
 ous suggestions that lamellipodia are driven by cycles of solation, osmot-
 ic expansion, and re-gelation of the actin filament network [22].
 Filopodia dynamics depend on diffusible cues from the environment as
 well as the nature of the substrate to which they adhere, as discussed
 below in *Filopodia dynamics and Filopodial FCs*. There is a possibility
 that cues such affect other protrusions but, if so, there is little indication
 of how the cues regulate their dynamics.

The knowledge of actin filament dynamics can be fit into a theoret-
 ical model that is consistent with physiological aspects discussed above.

Table 1
 Relation of factor values for protrusions to morphology of the cell edge.

Unbiased class	Value increases with increases in	
Factor #4	Prevalence of filopodia	t1.4
Factor #5	Centripetal mass distribution	t1.5
Factor #7	Prevalence of nascent neurites	t1.6
Factor #16	Features more massive than filopodia but pointed	t1.7
