Sub-nano-Pt clusters

Graphene nanosheet

CO tolerance

ABSTRACT

The carbon monoxide (CO) tolerance performance of polymer electrode fuel cells (PEFCs) was studied for a catalyst composed of graphene nanosheets (GNS) with sub-nano-Pt clusters. The Pt catalysts supported on the GNS showed a higher CO tolerance performance in the hydrogen oxidation reaction (HOR), which was significantly different from that of platinum on carbon black (Pt/CB). It is proposed that the presence of the sub-nano-Pt clusters promotes the catalytic activity and that the substrate carbon material alters the catalytic properties of Pt via the interface interactions between the graphene and the Pt.

1. Introduction

Graphene nanosheets (GNS) are promising carbon materials for a variety of energy technologies, including electrocatalysis, lithium ion batteries, hydrogen storage and capacitors. This is because they exhibit unique two-dimensional sheet structures and superior electrical conductivities when compared with graphitic carbon. GNS are obtained by the chemical reduction of graphite and are used for large scale applications [1–6]. We have reported that GNS exhibit giant Li-ion intercalation capacities reaching 784 mAh/g, in a reversible way, which is more than twice that of graphite [1,2]. Several groups have reported that metal nanoparticles such as Pt and Au, when supported on GNS, show high performances when used as electrocatalysts for fuel cells [3–7]. The enhanced performance of the electrocatalyst is attributed to the high specific surface area of the GNS. We have also reported that Pt catalysts supported on GNS show a high performance for methanol oxidation reaction (MOR) when compared with Pt/carbon black (Pt/CB). It has been suggested that this high performance for MOR is attributed to the formation of sub-nano-Pt clusters on GNS with average sizes of 0.3 nm. Pt particles of such a small size have not previously been

observed on carbon. The presence of sub-nano-Pt clusters on GNS has been thought to enhance the MOR activity [8]. It is therefore expected that GNS with sub-nano-Pt clusters will be excellent candidates for use as electrocatalysts in fuel cells. However, there have been no reports on the evaluation of electrocatalysts in polymer electrolyte fuel cells (PEFCs). Therefore, we have investigated the use of Pt/GNS as anode or cathode electrocatalysts for PEFCs. It is thought that the catalytic activity of Pt is promoted by using this new, unique carbon material, leading to a reduction in Pt usage, in PEFCs. The development of carbon monoxide (CO) tolerant catalysts is required for the commercialization of stationary type PEFCs, using hydrogen fuels produced from reforming hydrocarbons. It is widely recognized that Pt catalysts are deactivated by a small amount of CO and that Pt/Ru alloy catalysts are highly CO tolerant. We report here a catalyst composed of GNS with sub-nano-Pt clusters which show a high CO tolerance as an anode catalyst for PEFCs.

2. Experimental

Graphene nanosheets (GNS) were obtained via a solution-based route, involving the chemical oxidation of graphite to hydrophilic graphite oxide. Graphite oxides were made by the Hummers method [9]. Graphite oxides were easily exfoliated to form individual graphene oxide sheets, by ultrasonication in water. The graphene oxide sheets were then reduced to graphene nanosheets by use of hydrazine hydrate.

The 20 wt% Pt catalysts were deposited onto graphene nanosheets using a platinum precursor of $[\text{Pt}(\text{NO}_2)_2(\text{NH}_3)_2]$ (Ishifuku Metal Industry, Tokyo) in an ethanol solution. The powdered mixture was dispersed in ethanol, dried in air at 40 °C for 1 h and then subjected to heat-treatment in a hydrogen/Argon (H_2/Ar) (1:4, v:v) stream at 400 °C for 2 h in a furnace. Commercial 20 wt% Pt/CB and 20 wt% Pt-10 wt% Ru/CB catalysts (Johnson Matthey) were also tested for comparison. Transmission electron microscopy (TEM) images showed that well-dispersed Pt and Pt-Ru particles with sizes ranging from 2 to 3 nm were obtained for these commercial catalysts. The amount of Pt or Ru in the electrocatalysts was estimated by ICP (inductively coupled plasma) analysis.

The catalytic activity for a hydrogen oxidation reaction (HOR) was tested in a three-electrode glass cell, in 0.05 mol dm^{-3} H_2SO_4 at room temperature, under a flow of pure H_2 or in a mixture of 500 ppm CO/H_2 , in the solution for 1 h. Catalysts were loaded onto a glassy carbon disk electrode (0.28 cm^2) with diluted (1:50 in methanol) 5 wt% Nafion solution (Aldrich). The working electrode was a catalyst supported on a glassy carbon disk, the counter electrode was a platinum plate, and a silver/silver chloride electrode (Ag/AgCl) was used as the reference electrode.

CO_{ad} oxidation was measured by CO_{ad} stripping voltammetry, in a 0.05 mol dm^{-3} H_2SO_4 solution, at room temperature. 3% CO/N_2 gas was passed into the cell for 1 h. Then, the CO/N_2 gas was purged with N_2 gas for 30 min, and the CO_{ad} stripping experiment was performed at a scan rate of 10 mV s^{-1} . The hydrogen ionization measurements of the CO_{ad} -covered electrodes were performed by bubbling hydrogen gas for 30 min, to produce a saturated solution. Cyclic voltammetry was carried out in a flow of H_2 gas at a scan rate of 10 mV s^{-1} .

A durability test was performed, with repeated potential cycling, between -0.25 and 1.0 V vs. Ag/AgCl at 50 mV s^{-1} in N_2 saturated 0.05 mol dm^{-3} H_2SO_4 at room temperature.

The morphological structures of the Pt/GNS and the Pt/CB were characterized by High-Angle Annular Dark-Field Scanning Transmission Electron Microscopy (HAADF-STEM, JEOL, JEM-3000F).

3. Results and discussion

The prepared GNS revealed a curled morphology, consisting of a thin wrinkled paper-like structure as shown by the SEM images in Fig. 1(a). The thickness of the GNS was estimated to be between 3 and 7 nm by SEM measurements, corresponding to ca. 10–20 stacked layers of monatomic graphene sheets. In addition, as shown in the TEM images in Fig. 1, the thin GNS were irregularly bent and deformed like crumpled paper, and the graphene sheets were randomly stacked. The morphological structure, the particle size, and the metal dispersion of the Pt electrocatalysts were also examined by TEM. Fig. 1(c) and (d) shows the TEM images of Pt/GNS and Pt/CB, respectively. Pt particles with sizes of 2–3 nm for the Pt/GNS and Pt/CB were well-dispersed on the GNS and the CB. To observe sub-nano-Pt clusters, HAADF-STEM images were taken for both the Pt/GNS and the Pt/CB. Fig. 1(e) shows the image of the Pt/GNS and it can be seen that platinum is finely dispersed on the GNS with many clusters being less than 0.5 nm in diameter and with the largest being 2 nm wide. The image were also used to study the size of the smaller Pt clusters and these were estimated to be 0.3 nm. However, the HAADF-STEM measurements did not show any sub-nano-Pt clusters supported on the carbon black of the Pt/CB (Fig. 1(f)).

Fig. 2 shows the catalytic activities of the Pt/GNS, Pt/CB and PtRu/CB for the HOR reaction for 1 h at room temperature in pure H_2 and in H_2 with 500 ppm CO. In pure H_2 , the catalytic activities of all the samples were similar, regardless of the type of carbon material used. However, a significant support effect was observed

in the presence of H_2 with 500 ppm CO. The HOR activity of the Pt/GNS electrocatalyst remained at ca. 52% (0.44 mA cm^{-2}) of that in pure H_2 at -0.1 V vs. Ag/AgCl. In contrast, the Pt/CB electrocatalyst exhibited less than about 11% (0.13 mA cm^{-2}) of the catalytic activity in H_2 . In comparison, the PtRu/CB, which is a well-known CO tolerant catalyst, maintained a catalytic activity of up to 45% (0.54 mA cm^{-2}) under 500 ppm CO/H_2 . This clearly shows that the CO tolerance performance of the Pt/GNS is significantly superior to that of Pt/CB and that the substrate carbon material alters the catalytic properties of the Pt for the PEFCs.

To investigate the differences in the CO tolerance performance between the Pt/GNS and the Pt/CB, we examined the relationship between the onset potentials of the hydrogen ionization and the CO oxidation potentials of all of the measured samples. Fig. 3 shows the hydrogen ionization voltammograms on CO_{ad} -covered Pt as well as the CO stripping voltammograms. The anodic current of the CO_{ad} oxidation on the Pt/GNS starts to increase at about 0.40 V vs. Ag/AgCl and shows an anodic peak at 0.49 V vs. Ag/AgCl as shown in Fig. 3(a). If the H_2 ionization occurs on the free Pt sites formed by the removal of the CO_{ad} , the H_2 ionization of the Pt/GNS proceeds at 0.40 V vs. Ag/AgCl. This is the point at which CO_{ad} removal begins on the Pt. However, the H_2 ionization of the Pt/GNS was initiated at a lower voltage of 0.2 V vs. Ag/AgCl and attained a limiting current of 0.48 V vs. Ag/AgCl. In contrast, the PtRu/CB and Pt/CB catalysts showed hydrogen ionization on CO_{ad} -covered electrodes began at the same time as CO_{ad} removal started, in the CO stripping voltammograms, that is, at 0.2 and 0.42 V vs. Ag/AgCl, respectively. Kita et al. have reported that hydrogen ionization on Pt metal takes place on an extremely small number of vacant upd (underpotential deposition)-H sites and can easily attain a limiting current. This is because the H_2 ionization takes place at the remaining free sites, following the removal of the CO_{ad} [10]. The reasons why the Pt/GNS showed such a difference in behavior towards hydrogen ionization on CO_{ad} -covered Pt are not yet clear. However, we believe that the existence of the sub-nano-Pt clusters on the GNS may allow hydrogen ionization to take place on the CO_{ad} -covered Pt, in the low over-potential regions.

Fig. 4 shows the CO oxidation charges for the Pt/CB and Pt/GNS as a function of CO concentration. The CO/H_2 gases with CO concentrations of 500 ppm, 1% and 3% were passed into the cell for 1 h. The CO/H_2 gases were then purged with N_2 gas for 30 min, and CO_{ad} stripping voltammetry was performed at a scan rate of 10 mV s^{-1} in N_2 . The CO oxidation charge of the Pt/CB reached a full charge for the 500 ppm CO concentration. In contrast, we found that the CO oxidation charge of the Pt/GNS was approximately 10 times lower than that of the Pt/CB in a 500 ppm CO concentration. This indicated that the coverage of CO_{ad} on the Pt/GNS was relatively small at 500 ppm CO. The CO oxidation charge of the Pt/GNS reached a full charge at 1% CO concentration. These results suggest that the CO tolerant HOR activity of the Pt/GNS is greatly enhanced by the less reactive character of the Pt supported on GNS, toward CO adsorption.

The stability of the electrocatalysts is one of the most important factors because of the high demand for their long-term performance in fuel cells. This stability can be investigated by repeated potential cycling in acidic solution. We performed potential cycling between -0.25 and 1.0 V vs. Ag/AgCl at a scan rate of 50 mV s^{-1} , in N_2 saturated H_2SO_4 solution to examine the durability of both the Pt/GNS and Pt/CB towards the HOR. The electrochemically active surface area (ECSA) was estimated by the charge corresponding to the hydrogen desorption from the electrode surface [11]. The ECSAs for the Pt/GNS and Pt/CB were estimated to be 24.01 and 20.61 m^2/g Pt, respectively, before potential cycling. The reason why the ECSA of Pt for Pt/GNS is not so large is explained by the coexistence of larger Pt particles above 2 nm in size as shown in Fig. 1(c). Interestingly, the decrease in the ECSA value of the Pt/GNS is smaller than that of the Pt/CB, after potential cycling, as can be compared
