## ABSTRACT

There are observational and theoretical evidences both in favor of and against hydrodynamic escape (HDE) on Titan, and the problem remains unsolved. A test presented here for a static thermosphere does not support HDE on Titan and Triton but favors HDE on Pluto. Cooling of the atmosphere by the HCN rotational lines is limited by rotational relaxation above 1100 km and self-absorption below 900 km on Titan. HDE can affect the structure and composition of the atmosphere and its evolution. Hydrocarbon, nitrile, and ion chemistries are strongly coupled on Titan, and attempts to calculate them separately may result in significant errors. Here we apply our photochemical model of Titan's atmosphere and ionosphere to the case of no hydrodynamic escape. Our model is still the only after-Cassini self-consistent model of coupled neutral and ion chemistry. The lack of HDE is a distinct possibility, and comparing models with and without HDE is of practical interest. The mean difference between the models and the neutral and ion compositions observed by INMS are somewhat better for the model with HDE. A reaction of  $\text{NH}_2$  with  $\text{H}_2\text{CN}$  suggested by Yelle et al. (2009) reduces but does not remove a significant difference between the ammonia abundances in the models and INMS observations. Losses of methane and nitrogen and production and deposition to the surface of hydrocarbons and nitriles are evaluated in the model, along with lifetimes and evolutionary aspects.

## 1. Introduction

Self-consistent photochemical models are a powerful tool to study atmospheric chemical composition. These models fix the densities of parent species ( $\text{N}_2$  and  $\text{CH}_4$  for Titan) at the surface as boundary conditions in order to calculate vertical profiles of numerous photochemical products throughout the atmosphere. Currently, the only published post-Cassini self-consistent models for Titan's atmosphere are those by Lavvas et al. (2008a,b) and Krasnopolsky (2009), hereafter LCV and Paper I, respectively.

A partial photochemical model uses a chosen background atmosphere to calculate densities of some species but neglects effects of the calculated species on the background atmosphere. The choice of the background atmosphere in the partial models gives some degrees of freedom that facilitate fitting the calculated species to observations.

Ionospheric models are examples of a partial photochemical model. Ion–neutral reactions are usually much faster than reactions between neutral species in the upper atmosphere of Titan and can strongly affect the densities of some neutral species. Therefore, neglect of the reactions in models of Titan's

atmosphere may be a source of error. Of course each model is an approximation of reality, and some errors are inevitable. However, models with coupled neutral and ion chemistry have some advantages. There are currently two models of this type for Titan's atmosphere: the pre-Cassini model by Wilson and Atreya (2004, hereafter WA) and Paper I. A model by Banaszkiwicz et al. (2000) does include the ionosphere; however, hydrocarbons, nitriles, and ions were calculated separately in that model.

The model of Titan's atmosphere and ionosphere in Paper I is a convenient tool to study various hypotheses related to the atmospheric chemical composition. Here I investigate (1) the effect of a new reaction of  $\text{NH}_3$  formation proposed by Yelle et al. (2009), (2) consider two tests for hydrodynamic escape on Titan, Triton, and Pluto, and (3) compare versions of the model with and without hydrodynamic escape against INMS data (Cui et al., 2009; Magee et al., 2009; Waite et al., 2009).

## 2. Ammonia in Titan's thermosphere

The INMS ion spectrum averaged over the Cassini flyby T5 is of special interest because it was observed during a strong precipitation of magnetospheric electrons. The solar zenith angle was  $127^\circ$  at the closest approach at altitude 1027 km, that is, the conditions were nighttime. The averaged ion spectrum

E-mail address: [vkrasn@verizon.net](mailto:vkrasn@verizon.net)

(Vuitton et al., 2007) refers to a mean altitude of 1100 km. The spectrum was fitted by a local (i.e., without transport) ion chemistry model with densities of neutral species as fitting parameters. The densities of 19 species were retrieved (Vuitton et al., 2007) using this approach. Although the obtained densities are model-dependent to some extent, they originate in the measured ion spectrum.

Peaks at  $m/e=18$  in the ion spectra observed by INMS are due to  $\text{NH}_4^+$ . This ion forms in reactions of  $\text{NH}_3$  with other ions, and the derived ammonia mixing ratio is 6.7 ppm at 1100 km in Vuitton et al. (2007). Analysis of the INMS neutral spectra results in an even higher  $\text{NH}_3$  abundance of 30 ppm at 1077 km (Cui et al., 2009). This may be compared with an upper limit of 6 ppb for ammonia in the stratosphere from Voyager/IRIS spectra (Bernard et al., 2003). Clearly, ammonia forms in the upper atmosphere; however, the models predict much lower  $\text{NH}_3$  abundances near 1100 km than the INMS values: 0.4 ppm in Paper I, 0.2 ppm in LCV, and 0.04 ppm in WA.

The loss of  $\text{NH}_3$  through reactions with  $\text{HCNH}^+$  and  $\text{C}_2\text{H}_5^+$  in our model is perfectly balanced by the production of  $\text{NH}_3$  through recombination of  $\text{NH}_4^+$ , and we may thus neglect ion reactions in the  $\text{NH}_3$  balance. According to Paper I,  $\text{NH}_3$  forms in the upper atmosphere in reactions of N with  $\text{C}_2\text{H}_5$  and  $\text{C}_3\text{H}_6$ , and photolysis provides the only loss of  $\text{NH}_3$  (Fig. 1). This figure shows a significant difference between the production and loss of  $\text{NH}_3$  above  $\sim 500$  km that reflects transport by eddy and molecular diffusion.

To increase the production of ammonia, Yelle et al. (2009) suggested the reaction

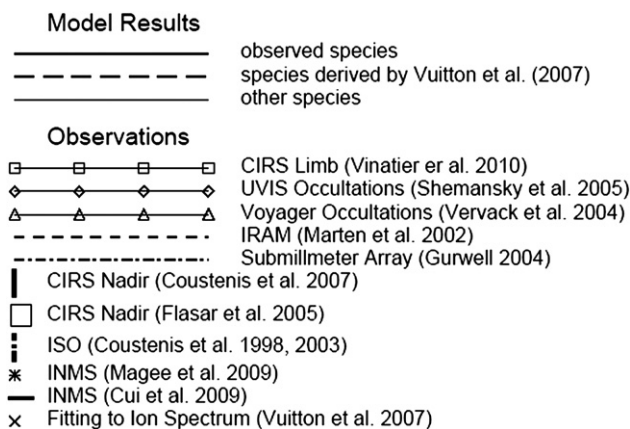

This reaction has not been studied in the laboratory, and its rate coefficient is unknown. This reaction may be compared to

with a rate coefficient of  $k = 10^{-10} e^{-200/T} \text{ cm}^3 \text{ s}^{-1}$  (Nesbitt et al., 1990). Since the bond energies of H in NH,  $\text{NH}_2$ , and  $\text{NH}_3$  are rather similar (3.54, 4.10, and 4.40 eV, respectively), and

**Fig. 1.** Main reactions of  $\text{NH}_3$  formation and loss. Ion reactions  $\text{NH}_3 + \text{HCNH}^+$ ,  $\text{C}_2\text{H}_5^+$  are perfectly balanced by recombination of  $\text{NH}_4^+$  and not shown.  $\text{NH}_3$  photolysis is shown for three versions of the model: without  $\text{NH}_2 + \text{H}_2\text{CN}$  (short dashes), inclusion of  $\text{NH}_2 + \text{H}_2\text{CN}$  (long dashes), and inclusion of both  $\text{NH}_2$  and  $\text{NH} + \text{H}_2\text{CN}$  (solid line). This photolysis reflects an increase in  $\text{NH}_3$  at 1100 km by factors of 2.3 and 2.5, respectively. The  $\text{NH}_2 + \text{H}_2\text{CN}$  reaction is shown without and with  $\text{NH} + \text{H}_2\text{CN}$  (dashed and solid lines, respectively).

**Fig. 2.** Designations for comparison of the model results with the observations (Coustenis et al., 1998,2003,2007; Flasar et al., 2005; Gurwell, 2004; Marten et al., 2002; Shemansky et al., 2005; Vervack et al., 2004; Vinatier et al., 2010).

the masses of N, NH, and  $\text{NH}_2$  are close; we adopt the above rate coefficient for the reaction of  $\text{NH}_2 + \text{H}_2\text{CN}$ .

Ammonia production at 1100 km increases by a factor of 4 with this reaction (Fig. 1), while its density increases by a factor of 2.3. Photolysis of  $\text{NH}_3$  is mostly due to the near UV solar flux, Titan's atmosphere is transparent above the haze in this range, and the  $\text{NH}_3$  photolysis rates in Fig. 1 show variations of the ammonia density. The increase in density is smaller than the increase in production due to molecular and eddy diffusion.

NH is mostly formed in the upper atmosphere by the reactions of  $\text{N}(^2\text{D})$  with some hydrocarbons and is more abundant than  $\text{NH}_2$  above 900 km (Paper I). The reaction

may add to the production of  $\text{NH}_2$  and therefore  $\text{NH}_3$ . This reaction has not been studied in the laboratory either, and we likewise adopt  $k = 10^{-10} e^{-200/T} \text{ cm}^3 \text{ s}^{-1}$  for its rate coefficient. Its rate exceeds that of  $\text{NH}_2 + \text{H}_2\text{CN}$  by a factor of 5 (Fig. 1); however, the increase in  $\text{NH}_3$  abundance from this reaction is just 10%.

As mentioned above, these reactions enhance the abundance of  $\text{NH}_3$  at 1100 km by a factor of 2.5 to a value of 1.0 ppm. This is still significantly below the values retrieved from the INMS ion and neutral spectra (Vuitton et al., 2007; Cui et al., 2009). Thus, inclusion of these reactions reduces but does not remove the difference in ammonia abundances observed by INMS and calculated in the photochemical models. Yelle et al. (2009) discuss possible effects of heterogeneous chemistry on  $\text{NH}_3$ ; however, investigating such effects is currently beyond our model. The significant difference between ammonia abundances retrieved from the INMS spectra in the neutral and ion modes, 30 and 6.7 ppm, may also indicate some problems in the  $\text{NH}_3$  measurements.

### 3. Controversy of hydrodynamic escape

The  $\text{CH}_4/\text{N}_2$  ratio observed in Titan's upper atmosphere by INMS was unexpectedly low (Yelle et al., 2006), and this can be explained by either very strong eddy diffusion or strong escape of methane. Yelle et al. (2008) compared the INMS detection of  $^{40}\text{Ar}$  at a mixing ratio of 12 ppm near 1050 km with the  $^{40}\text{Ar}$  mixing ratio of 43 ppm measured in the lower atmosphere by the GCMS on the Huygens probe (Niemann et al., 2005); this results in an eddy diffusion coefficient  $K = 3 \times 10^7 \text{ cm}^2 \text{ s}^{-1}$  in the upper atmosphere, and the upward flux of methane required to fit
