### ABSTRACT

Within the BCS framework generalized Fermi surface topologies, modeled with band overlapping, are proposed as a mechanism to enhance the electronic density of states at the Fermi level. This band overlapping allows the high- $T_c$  values observed in cuprate superconductors at different pressures. With this approach the correlation between the critical temperature, the charge carrier density and the pressure is obtained in terms of the coupling constant and the band overlapping parameter. In order to obtain numerical results the model is applied to a TI-based superconductor.

### 1. Introduction

At present it seems well established that the superconducting and normal state properties of high- $T_c$  cuprates and other related ceramic compounds depend strongly on the charge carrier density. It is commonly believed that the charge carriers responsible for the superconducting pairing of many high- $T_c$  cuprates are holes mainly confined to the  $\text{CuO}_2$  layers [1]. The charge carrier density  $n_h$  is defined as the number of holes per  $\text{CuO}_2$  layer. Taking this property into account a two-dimensional (2D) fermion gas is a good model for high- $T_c$  cuprates.

The principal experimental results in cuprates related to the charge carrier density can be summarized with the following points [2]: at atmospherical pressure, the concentration of charge carriers in the  $\text{CuO}_2$  planes can be changed either by changing the oxygen concentration or by substituting some suitable element in the charge reservoir layers which lie between the  $\text{CuO}_2$  planes. Experimentally,  $n_h$  can be changed by preparing various samples with different doping. The critical temperature  $T_c$  depends on the carrier concentration and for most cuprates it is generally accepted that it obeys an inverse parabolic relation with the hole

concentration  $n_h$ . The maximum  $T_c$  ( $T_{c\text{max}}$ ) appears at the optimal carrier concentration,  $n_{\text{hop}}$ . Compounds with lower  $n_h$  are said to be underdoped while compounds with higher  $n_h$  are said to be overdoped.

On the other hand, the high- $T_c$  cuprate superconductors (HTSC) have been extensively studied under high pressures [3,4]. The pressure is an important parameter capable of increasing the  $T_c$  of several HTSC. However, this is not a general trend for all HTSC. It is known both from experiments and calculations that the application of high pressures is a useful mechanism to modify the charge carrier concentration  $n_h$ .  $T_c(p)$  is expected to follow a parabolic curve, which is indeed observed for a number of compounds [5]. This parabolic behavior can be different in some high- $T_c$  superconductors in which nonequivalent superconducting layers are present due to the peculiarities of the crystallographic structure. Nevertheless, pressure can increase  $T_{c\text{max}}$  to a value higher than the one obtained at any doping under atmospherical pressure, implying that there exists an intrinsic enhancement of  $T_c$  due to pressure. The resulting  $T_c(p)$  of every compound is determined by the combination of these effects, which provide important clues to the existence of superconductivity at higher temperatures.

High-pressure experiments can be done to find new materials and to test theoretical models, since the pressure dependence of  $T_c$  must be predicted correctly by the theory. The hydrostatic pressure modifies the lattice parameters taking into account the

specific compressibility of each HTSC under pressure; it is widely noted that these parameters are intimately related to the nature of the electronic band structure of the superconducting cuprates. Additionally, first principle calculations show overlapping energy bands at the Fermi level [6]. The short coherence length observed in high  $T_c$  superconductors has been also related to the presence of overlapping energy bands [7].

The predominant dependence of  $T_c$  on the electronic density of states (DOS) on the proximity and at the Fermi level is supported by numerous experiments. An increase in DOS favors higher  $T_c$  values. In order to increase the DOS for the 2D system at the Fermi level, a generalized Fermi surface with two overlapping bands is proposed as a prototype to describe multiband HTSC [8]. The energy band overlapping modifies the DOS near the Fermi level allowing the high  $T_c$  values observed. A similar effect can also be obtained with other mechanisms as a van Hove singularity in the DOS [9].

In this work, a simple schematic form of these generalized surface structures is proposed for a 2D fermion system. Within the BCS framework, a generalized Fermi surface with two overlapping bands is proposed. This model is applied to study the behavior of HTSC with equivalent  $\text{CuO}_2$  layers, i.e. with only one kind of charge carriers, in order to separate doping and intrinsic effects on  $T_c$  under pressure. Different doping and high pressures are considered. An important issue to address is how the variation of pressure affects the bands overlapping so that  $T_c$  increases.

## 2. Theory

A generalized Fermi sea of concentric shells of occupied orbitals is considered. The basic hypothesis of the model with two overlapping bands is introduced by the following particular distribution in momentum space:

$$n_k = \Theta(\gamma k_F - k) + \Theta(\gamma k_F - k)\Theta(k - \beta k_F), \quad (1)$$

with  $k_F$  the Fermi momentum, and  $0 < \beta < \gamma < 1$ . The distribution in momentum space induces one in energy,  $E_\beta = \beta^2 E_F < E_\gamma = \gamma^2 E_F$  [8].  $E_F$  is the Fermi energy. There is only one independent parameter because they must satisfy  $2\gamma^2 - \beta^2 = 1$  to keep the average number of electron states constant. Then  $\gamma^2$  is the overlapping parameter, if  $\gamma^2 = 1$  the distribution in momentum space reduces to the normal one.

The gap equation at  $T = T_c$  is the starting point. In this approach, an integral related to each band is obtained.

$$1 = \frac{\lambda}{2} \int_{\gamma^2 E_F - E_D}^{\gamma^2 E_F + E_D} \tanh\left(\frac{E - E_F}{2k_B T_c}\right) \frac{dE}{E - E_F} + \frac{\lambda}{2} \int_{(2\gamma^2 - 1)E_F}^{E_F} \tanh\left(\frac{E - E_F}{2k_B T_c}\right) \frac{dE}{E - E_F}, \quad (2)$$

where  $\lambda = V_0 D(E)$  is the coupling parameter, with  $D(E)$  the DOS of a bidimensional system.  $k_B$  is the Boltzmann constant,  $E_F = (\hbar^2 \pi / m) n_{2D}$ , with  $n_{2D}$  the number of carriers per  $\text{CuO}_2$  layer. The phonon-mediated effective interaction is considered to be a constant  $V = V_0$  within a range of the order  $E_D = \hbar \omega_D$  at  $E_\gamma$ , and zero elsewhere. Here  $E_D$  and  $\omega_D$  are the Debye energy and the cutoff frequency for phonon-mediated superconductivity, respectively.

The integration in the surface at  $E_\gamma$  in the first band is restricted to states in the interval  $E_\gamma - E_D \leq E_k \leq E_\gamma + E_D$ . In the second band, in order to conserve the particle number, the integration is restricted to the interval  $E_\beta = (2\gamma^2 - 1)E_F \leq E_k \leq E_F$ , if  $E_\gamma + E_D > E_F$ , while  $E_F - E_\gamma \leq E_D$  implies that the energy difference between the anomalously occupied states must be provided by the material itself. Then the overlapping parameter  $\gamma^2$  must be in the

range  $\gamma_D^2 \leq \gamma^2 < 1$  where the minimum overlapping parameter  $\gamma_D^2 = 1 - E_D/E_F$  is determined by the Debye limit. It means that the maximum overlapping is given by  $1 - \gamma_D^2$ .

After the integration, a relationship between  $\lambda$  and the characteristic parameters  $\gamma^2$ ,  $T_c$  and  $T_F$  can be obtained for high- $T_c$  compounds. It is possible to obtain a numerical exact solution or an approximate analytical expression for these integrals [10]. In any case a specific material must be selected to introduce the available experimental data. Ranges for the coupling parameter  $\lambda$ , and the overlapping parameter  $\gamma^2$ , consistent with the model and the experimental data, can be obtained for each material.

## 3. Results

In this work, characteristic properties of HTSC are evaluated. The two overlapping band model has been applied to describe HTSC with different number of layers [10]; however, in order to separate doping and intrinsic effects on  $T_c$  under pressure a system with only one kind of charge carriers in the  $\text{CuO}_2$  layers must be considered,  $n_{2D} = n_h$ .

A systematic investigation of  $\text{Tl}_{0.5}\text{Pb}_{0.5}\text{Sr}_2\text{Ca}_{1-x}\text{Y}_x\text{Cu}_2\text{O}_7$  was carried out by Liu [11]. They changed the charge carrier density  $n_h$  of the  $\text{CuO}_2$  layers by adjusting the doping  $x$ . This system exhibits superconductivity over the entire range from  $x = 0$  to 0.6. The maximum  $T_c$  is obtained at  $x = 0.21$ . Thus, samples at atmospheric pressure were available at different points on the  $T_c(x)$  curve. Initially, the model proposed here is applied to study the behavior of this material with different doping.

The possible  $T_c$  values for this cuprate, from Eq. (2), that the model with two overlapping bands can predict at atmospheric pressure are calculated. In Fig. 1,  $T_c$  as function of  $\lambda$  in the weak coupling regime  $\lambda \leq 0.58$  is shown. Different  $\gamma^2$  values in the range  $1 < \gamma^2 \leq \gamma_D^2$ , for  $n_{2D} = n_{\text{hop}} = 0.16$  [12], were considered. The continuous curve shows the relationship between  $T_c$  and  $\lambda$ , with maximum overlap,  $\gamma^2 = \gamma_D^2 = 0.88$ , for this carrier density. The other curves are calculated at intermediate overlaps, the small dashed curve with  $\gamma^2 = 0.94$  and the large dashed one with  $\gamma^2 = 0.96$ . Consistent with the maximum experimental  $T_c$  value for  $\text{Tl}_{0.5}\text{Pb}_{0.5}\text{Sr}_2\text{Ca}_{1-x}\text{Y}_x\text{Cu}_2\text{O}_7$  obtained at atmospheric pressure we obtain, with all these overlapping parameters, a  $T_c = 105$  K at  $\lambda = 0.5, 0.52$  and 0.56, respectively. All the curves are strictly increasing with  $T_c$ : then for a given overlap the system requires bigger  $\lambda$  values to reproduce higher  $T_c$  values. From this figure it is

**Fig. 1.**  $T_c$  as a function of the coupling parameter  $\lambda$ , with  $n_{2D} = 0.16$  for  $\text{Tl}_{0.5}\text{Pb}_{0.5}\text{Sr}_2\text{Ca}_{1-x}\text{Y}_x\text{Cu}_2\text{O}_7$ . The continuous curve shows the results with  $\gamma^2 = \gamma_D^2$ .  $T_c = 105$  K is obtained at  $\lambda = 0.5$ , consistent with the maximum experimental  $T_c$  value for this cuprate. The other curves, from top to bottom, are calculated with  $\gamma^2 = 0.94$  and 0.96.
