Methicillin-resistant *Staphylococcus aureus* (MRSA)

SUMMARY

Objective: *spa*-typing of methicillin-resistant *Staphylococcus aureus* (MRSA) has been used widely in clinical diagnostics and epidemiological studies. The aim of this study was to evaluate high-resolution melting (HRM) as a rapid and cost-effective method, to replace DNA-sequencing, for *spa*-typing in a global collection of 50 MRSA isolates.

Methods: The polymorphic X region of the *spa* gene was amplified by colony PCR using the SensiMix HRM kit, and the melting temperature (*T_m*) and melting curves of the amplicons were analyzed in close tubes using a Rotor-Gene 6000 instrument.

Results: Fifteen out of 19 *spa*-types each had a distinct *T_m*, which was sufficient to unambiguously type each of these *spa*-types. The remaining four *spa*-types could not be separated by *T_m* alone: t008 and t2770 shared a *T_m* (80.3 °C) and t021 and t311 shared a *T_m* (80.0 °C). However, they could be separated based on the shapes of their melting curves. There are discrepancies between the findings of the present study and those of previous studies, suggesting that standardization remains a challenge for cross-referencing.

Conclusion: HRM-based *spa*-typing is reproducible, simple, rapid, and cost-effective. t037 is prevalent in Brazil and Sudan, while diverse *spa*-types are found in Scotland and Saudi Arabia. Standardization is required for cross-referencing between laboratories globally.

1. Introduction

Methicillin-resistant *Staphylococcus aureus* (MRSA) remains a major cause of infection in the community and healthcare settings, and poses a significant threat to public health.^{1,2} Molecular typing methods are vital for the rapid identification of prevalent strains, which is important for active surveillance and to control the spread of disease. The polymorphic region of the gene encoding staphylococcal protein A (*spa*) has been found to be highly discriminatory and is useful for investigating both the local and global epidemiology of *S. aureus*.^{3–9} The complexity and high running cost of PCR sequencing have limited its use in developing countries.¹⁰ Recently, high-resolution melting (HRM)-based *spa*-typing has been described as a rapid and cost-effective method for genotyping locally predominant

isolates.^{10,11} To test the accuracy and reliability of HRM-based *spa*-typing, a global collection of 50 MRSA isolates was analyzed in the present study. HRM was demonstrated to accurately *spa*-type the majority of these isolates.

2. Materials and methods

2.1. MRSA isolates

Fifty clinical MRSA isolates collected between 2005 and 2012 were selected randomly from Scotland ($n = 22$), Brazil ($n = 13$), Sudan ($n = 3$), and Saudi Arabia ($n = 12$). All isolates were cultured and identified as *S. aureus*, as described previously.¹² The methicillin resistance phenotype was confirmed in accordance with the British Society for Antimicrobial Chemotherapy (BSAC) standards using the Vitek 2 system (bioMérieux, USA). An isolate was considered as methicillin-resistant when the minimum inhibitory concentration (MIC) breakpoint of oxacillin was >2 mg/l and cefoxitin >4 mg/l.¹³

HRM, high-resolution melting; MRSA, methicillin-resistant *Staphylococcus aureus*; *Tm*, melting temperature.

^a Note: *spa*-types in bold share the same *Tm*. These could be differentiated by the shapes of the melting curves, as shown in Figure 2.

2.2. DNA sequencing for *spa*-typing

The polymorphic regions of the *spa* gene were amplified and sequenced for all isolates, as described previously.^{5,14} The sequence data were analyzed using the *spa*-typing plug-in in BioNumerics v. 5.1 (Applied Maths).

2.3. HRM analysis for *spa*-typing

The polymorphic X region of the *spa* gene was amplified in a Rotor-Gene 6000 instrument (Qiagen) by colony PCR using a SensiMix HRM kit (BioLine), as described previously by Shopsis et al.³ In brief, a 20- μ l PCR reaction was set up, containing 0.8 μ l Eva-Green, 10 μ l SensiMix, 1 μ l of each primer (100 μ M; 1095 forward 5'-AGACGATCCTTCGGTGAGC-3' and 1517 reverse 5'-GCTTTTGCAATGTCATTTACTG-3'), and 20 ng of the template DNA; this was programmed as follows: a hold at 95 °C for 10 min, followed by 35 cycles of 95 °C for 20 s, 56 °C for 20 s, and 72 °C for 22 s. The high-resolution melting analysis of the amplicons was performed between 70 and 95 °C with a stepwise increase of 0.05 °C. The melting temperatures (*Tm*) were determined by the negative derivative of decreased fluorescence over increased temperature (df/dt), using the proprietary software (version 1.7.34). The shapes of the melting curves were viewed with the same software.

3. Results and discussion

By use of DNA sequencing and the *spa*-typing plug-in in BioNumerics, 19 *spa*-types were identified among the 50 isolates. *spa*-type t037 was the major *spa*-type that was prevalent among Brazilian (12/13 isolates) and Sudanese isolates (3/3 isolates). Scottish and Saudi Arabian isolates were quite diverse; eight *spa*-types were observed among 22 isolates from Scotland and nine *spa*-types among 12 isolates from Saudi Arabia (Table 1).

All 50 isolates were then subjected to HRM analysis. Fifteen out of the 19 *spa*-types each had a distinct *Tm* that unambiguously assigned 44 isolates (Table 1, Fig. 1). The melting curve within a *spa*-type was highly homogeneous. However, despite the difference in GC content between t008 and t2770 (43.7 mol% and 41.5 mol%, respectively), these *spa*-types shared the same *Tm* (80.3 °C; Fig. 2A). Similarly, t021 and t311 could not be separated from each other; they shared a *Tm* of 80.7 °C. This is probably due to the fact that they have the same GC content (44.9 mol%) (Fig. 2B).
