Mastectomy

## ABSTRACT

This report discusses the case of a chyle leak following a right axillary lymph node dissection for breast cancer. This presented as a sudden change in drainage character from a right axillary surgical drain from serous to milky white shortly after restarting a diet. The diagnosis of chyle leak was confirmed by laboratory testing of the fluid and managed with closed suction drainage. Chyle leak is a rare, but increasingly recognized complication following axillary clearance for breast cancer and melanoma.

## 1. Introduction

Chyle leak is a well recognized complication among surgeons, most frequently being encountered following radical neck dissection or intrathoracic procedures [1,2]. However, very few surgeons are familiar with the potential for chyle leak as it exists in the setting of breast cancer/reconstruction. Typically attributed to injury of the thoracic duct, chyle leaks can be diagnosed based on the clinical presence of milky, non-purulent fluid drainage with laboratory tests serving as a useful adjunct in questionable cases. Management is usually conservative consisting of dietary modifications, adequate drainage and pressure dressings; however surgical intervention has also been advocated in certain cases [3]. We present a case of a chyle leak following a right axillary lymph node dissection and discuss the management and considerations therein.

## 2. Case report

A 41-year-old female was seen following diagnosis of right breast cancer. The patient had a family history of BRCA1 positive breast cancer. The patient elected to undergo bilateral skin sparing mastectomies with right-sided sentinel lymph node biopsy and immediate tissue expander reconstruction. Intraoperatively patient was found to have 2 of 4 sentinel nodes positive for dis-

ease and underwent a standard level I and II right axillary lymph node dissection. Following completion of the axillary dissection, the wound bed was felt to be dry without any noted bleeding or lymphatic leakage. The remainder of the operation, including placement of bilateral tissue expanders, was completed without complication. A drain was left on each side.

On the first post-operative day patient was noted to have serosanguinous drainage from both drains with the right draining roughly 80 cc over an 8-h period compared to 30 cc on the left. Patient was started on a regular diet beginning at noon. Roughly 4 h following patient's first full meal the drainage in the right drain was noted to have abruptly changed to a milky color. Triglyceride level was sent on the milky drainage and was 749 mg/dl, suggesting a chyle leak. The drainage remained low output and patient was continued on a regular diet. Over the following 2 days the output of both drains decreased and the right becoming gradually less chylous in nature. The patient was discharged home with drains in place. Following discharge, the prior chylomicron screen of the right drain fluid returned positive, confirming a right sided-chyle leak. The patient was seen eleven days post-operatively and both drain outputs were noted to be serosanguinous in nature and were removed. At no point during her course did she develop any fluid collection in the right axilla.

## 3. Methods

A MEDLINE search was completed using the medical subject headings (MeSH) 'axillary dissection' and 'chyle' and hand searching the references. The references of each article were then

examined to identify any relevant literature missed by the initial search. Each case report was examined for laterality, tumor stage, level of axillary clearance, the interval between surgery and diagnosis of chyle, the duration of the chyle leak, the volume of chyle during the first 24 h, the median volume and the administered treatment. This work is reported in line with CARE criteria [4].

#### 4. Results

A total of 15 articles published in English were identified ranging in publication from 1993 to 2011 [5–19]. (Table 1). A total of 37 patients, including the current case, were included (36 female, 1 male). Reason for axillary clearance included breast cancer (36 patients) and malignant melanoma (1 patient). 92% (34/37) of leaks were identified on the left side. There was no correlation found between clearance level and the volume of the chyle leak. The majority of leaks were identified in the first two post-operative days (Fig. 1). 89% (31/35) of cases resolved with conservative management; 4 patients required operative intervention. Patients requiring operative intervention had an average median daily drainage of 700 cc/day compared to 183 cc/day among those with successful conservative treatment. The average time to resolution in patients successfully treated conservatively was 12.1 days. The day of onset did not correlate with the duration of the leak.

#### 5. Discussion

Chyle leak following axillary lymph node dissection is a rarely reported complication. Several small cases series have reports incidences ranging from 0.36% to 0.84% [5–8]. The majority (86%) present within the first 3 days following surgery [9].

##### 5.1. Mechanism

The mechanism for axillary chyle leak is poorly understood at this time. Chyle leaks are generally felt to result from injury of the thoracic duct. However the thoracic duct typically ascends through the chest and abdomen adjacent to the spine, crossing to the left of midline at the level of the aortic arch and finally terminating in the venous system at the base of the left neck. The majority of the variability seen in the thoracic duct involves its termination into one of several veins including: the internal jugular, external jugular, subclavian and innominate veins [20]. However, some studies have demonstrated branching of the duct in up to 30% of cases [20] and multiple terminations into the venous system in 4% of cases [21,22]. This has led some authors to theorize that axillary chyle leaks are due to injury to an aberrant branch of the thoracic duct, [9] with drainage to the left axilla [23]. Singh et al. suggest there could be

reflux of chyle through the lymphatics if the subclavian duct were to insert on the thoracic duct [17].

The vast majority of chyle leaks were noted to occur in the left axilla as would be expected given the termination of the thoracic duct in the left venous angle and the theoretical isolation of the right upper extremity lymphatics. However, Cong et al. [8] reported two cases of right-sided chyle leaks following axillary lymph node dissection with this case representing the third occurrence in the literature. Right-sided chyle leaks have also been rarely reported following though again with great rarity [24]. This occurrence is attributed to anatomic variants of the thoracic duct including paired ducts, a single right-sided duct or bilateral branching of the upper duct. All of these variants are well documented in the literature [25].

##### 5.2. Diagnosis

The diagnosis of a chyle leak is a clinical one based on the presence of milky white drainage. This drainage typically increases with high fat meals and resolves with fasting. Laboratory testing can be used as an adjunct with examination of the fluid for triglycerides, cholesterol, protein, lipid electrophoresis, cell counts and pH [26–29]. (Table 2) Lymphoscintigraphy has also been demonstrated as an effective diagnostic adjunct [21].

The majority of chyle leaks following axillary dissection were discovered on post-operative day 1 or 2 [9]. This corresponds to the patients return to PO diet and the absorption of triglycerides with subsequent formation of chylomicrons within the villous lymphatics. As the patient is in a fasting state intra-operatively without significant production of chylomicrons/chyle, intra-operative detection is uncommon. Singh et al. [17] reported intra-operative detection at the time of initial surgery in 2/6 patients, observing that both had been early morning cases. They were also able to identify a leak intra-operatively on re-exploration of a patient after intentionally feeding them a high fat meal immediately prior to being placed NPO. Several other authors have recommended a 6–8 oz mixture of milk and cream or olive oil given to the patient a few hours before surgery in order to help identify the leak at the time of operation [30,31].

##### 5.3. Management

The majority of reported cases were managed successfully with conservative measures including: low-fat diet, pressure dressing, and negative pressure drainage. In cases of continued high output drainage the patient can be placed NPO and parenteral nutrition begun. Traditionally medium-chain triglyceride (MCT) diets were also recommended, however, more recent studies have questioned the utility this practice [32]. Suitable enteral formulas are well described in the dietary literature [33]. The use of octreotide has been described for chylous ascites or mediastinal thoracic duct injuries [34–36]. Leakage after neck dissection has been treated with a local injection of tetracycline hydrochloride [37].

In the setting of persistent leakage re-exploration and attempted ligation of the leak is recommended. Merrigan et al. [31] proposed surgical intervention when leakage persists for more than 2 weeks, drainage volume is more than 1 L/day even after 1 week, or the patient has started to experience metabolic complications. Crumley and Smith [3] and Spiro et al. [1] suggest intervention when the leakage is more than 500–600 mL/day. Direct control with suture ligation and clip application are mainstays in treatment. Various topical agents including gel foam, oxidized cellulose, and methyl-2-cyanoacrylate (tissue glue) have also been described. Two authors [17,19] have described coverage of leak with pectoralis muscle flaps.
