## ABSTRACT

Accurate prediction of boundary layer transition is extremely important for the aerodynamic and aerothermodynamic design of a hypersonic vehicle. Crossflow instability plays a crucial role in inducing transition in three-dimensional (3D) boundary layer. In this paper, a crossflow timescale  $\tau_{\text{cross}}$  based on crossflow velocity and crossflow Reynolds number is proposed and incorporated into the  $k$ - $\omega$ - $\gamma$  transition model. Additionally, a grid pretreating method that can calculate boundary layer parameters with massive parallel execution is also proposed. HIFiRE-5, circular cone at angle of attack and X-33 vehicle are considered as test cases to assess the performance of the improved  $k$ - $\omega$ - $\gamma$  transition model. Simulation results demonstrate that the boundary layer edge of complex hypersonic 3D flow can be obtained accurately with the help of grid pretreating method. It has been shown that if crossflow is taken into consideration, the shapes and locations of the transition onsets predicted by the improved  $k$ - $\omega$ - $\gamma$  transition model are more consistent with experimental and direct numerical simulation results compared to the original transition model. This indicates that the improved  $k$ - $\omega$ - $\gamma$  transition model provides significant improvement when crossflow-induced transition in hypersonic 3D boundary layer flow is predicted. Furthermore, application of the improved  $k$ - $\omega$ - $\gamma$  transition model to X-33 vehicle flow shows that this model can be successfully used to predict crossflow-induced transition on complex full aircraft hypersonic configuration.

## 1. Introduction

It is extremely important to predict boundary layer transition accurately when thermal protection system, drag reduction, propulsive efficiency and stability of hypersonic vehicles are estimated [1]. Excellent reviews of hypersonic boundary layer transition have been given by Stentson and Kimmel [2], Malik [3], Morkovin and Reshotko [4], Fedorov [5] and so on. The hypersonic boundary layer flow is always three-dimensional (3D) due to the swept wing, the angle of attack and the non-axisymmetric configuration. Crossflow instability plays a crucial role in inducing a transition in this case. Bippes [6], Arnal and Casalis [7], Saric et al. [8] have provided comprehensive reviews of crossflow-induced transition on subsonic swept wing. Fig. 1 shows a scheme of crossflow-induced transition on an infinite swept wing [9]. In swept wing flows, with the combined effects of sweep angle  $\Lambda$  and spanwise pressure gradient, the external streamlines at the boundary-layer edge develop curvature in the planes parallel to the wing surface. Thus, centrifugal force occurs as a result of curved streamlines and radial pressure gradient occurs to over-balance this centrifugal force. As static pressure is assumed to be constant in the wall-normal direction within a boundary layer, the secondary flow in the spanwise direction is generated by radial pressure gradient at the boundary layer edge. Thus, a crossflow velocity component is produced [9]. Crossflow velocity at both the no-slip wall and the

boundary layer edge is equal to zero and its profile has an inflection point as shown in Fig. 1. Thus, the crossflow is subject to inviscid instability which can induce the transition process in 3D boundary layer. Neglecting the crossflow instability effects in 3D boundary layer flow simulations can lead to inaccurate transition prediction. Therefore, it is essential to take into account this important mechanism when predicting 3D boundary layer transition.

There are a variety of transition prediction methods such as  $e^N$  method, transition models, engineering correlations, direct numerical simulation (DNS) and large eddy simulation (LES). Transition
