This is a PDF file of an unedited manuscript that has been accepted for publication. As a service to our customers we are providing this early version of the manuscript. The manuscript will undergo copyediting, typesetting, and review of the resulting proof before it is published in its final form. Please note that during the production process errors may be discovered which could affect the content, and all legal disclaimers that apply to the journal pertain.

Highlights:

- We considered city level networks as deduced from mobile call records, this way arriving at a distribution of connected components of different sizes. Using SI, the simplest spreading model, we studied spreading if only intra-city links were used and compared this situation with the case, when additional links participated in the process.
- We have found that, in spite of the complex structure of the empirical networks (broad degree distribution, communities), it is the average degree, which mainly determines the spreading speed.
- Introduction of bridges through inter-city and unidentified links, as well as presence of large degree nodes boosts spreading;
- Our model calculations suggest that community structure and regularity slows down the spreading. Moreover, bursty interaction patterns results in faster spreading compared to homogeneous exponential inter-event times.
