#### Abstract

The $\left(2^{\prime} Z\right)$-configuration of roridin $J(1)$ was revised to the $\left(2^{\prime} E\right)$ form by conducting NOE experiments. Although the configurations with respect to the stereogenic carbons on the macrocyclic ring of $\mathbf{1}$ had remained unknown, a combination of NMR analysis and molecular modeling calculations revealed the $\left(2^{\prime} E, 5^{\prime} R, 6^{\prime} S, 7^{\prime} E, 9^{\prime} Z, 13^{\prime} S\right)$ form. In addition, the modeling calculations successfully reproduced the ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ NMR chemical shifts as well as the ECD spectrum. An X-ray crystallographic analysis verified all the relative configurations.

## 1. Introduction

Trichothecenes carrying macrocyclic rings, such as roridins, ${ }^{1,2}$ verrucarins, baccharins, ${ }^{3,4}$ and muconomycins, ${ }^{5}$ have been isolated from fungal sources, such as the Myrothecium and Fusarium species. In addition to unique structures, these exhibit potent antifungal, ${ }^{6,7}$ lethal, ${ }^{8}$ and/or cytotoxic ${ }^{9-11}$ properties. Accordingly, this family has attracted attention of the organic chemists and biological scientists. ${ }^{1,12,13}$ Although a comprehensive biological investigation requires well-established three-dimensional structures, the configurations of the macrocyclic moiety in some roridin congeners, e.g., roridin J (1) were not determined (Fig. 1). While exploring the fungal secondary metabolites, we had an opportunity to isolate $\mathbf{1}$ from Calcarisporium arbuscular, which led us to fully determine its stereostructure using a combination of spectral analysis and molecular modeling calculations. We succeeded in not only revising the configuration of the $\mathrm{C}^{\prime}{ }^{\prime} \mathrm{C}^{\prime}$ double bond but also establishing all configurations of asymmetric centers on the macrocycles. The proposed configuration was confirmed by an X-ray crystallographic diffraction analysis.

## 2. Results and discussion

Roridin J (1) was isolated from the culture broth of C. arbuscula. The ${ }^{13} \mathrm{C}$ NMR spectral data of our sample were coincident with those reported by Jarvis in $1980\left(\max \left|\Delta \delta^{13} \mathrm{C}\right|: 0.1 \mathrm{ppm}\right.$, both in $\left.\mathrm{CDCl}_{3}\right){ }^{14}$ Although Jarvis reported a potent NOE between $\mathrm{H}_{3}-12^{\prime}$ and $\mathrm{H}-2^{\prime}$ to conclude the $\left(2^{\prime} Z\right)$ form for the original structure of roridin $\mathrm{J}\left(\mathbf{1}^{\prime}\right)$, irradiation of $\mathrm{H}-2^{\prime}$ resulted a remarkable signal enhancement at $\mathrm{H}-4^{\prime}(13 \%)$ in our experiment, while that at $\mathrm{H}_{3}-12^{\prime}$ was not obvious (1.3\%), as shown in Fig. 2. This result allowed us to revise that into the $\left(2^{\prime} E\right)$ configuration shown as $\mathbf{1}$. The chemical shift for C12' ( 13.26 ppm ) supported our revision by taking account of the steric compression effect due to the $\mathrm{C} 1^{\prime}$ carbonyl group. ${ }^{15}$ Methyl carbons on the trisubstituted Z-double bonds usually resonate at 22-27 ppm, while those of corresponding E-isomers appear at around $5-10 \mathrm{ppm}$ lower frequency. This was further verified through chemical shift calculations, as described later.

Although several trichothecenes carrying macrocyclic rings have been reported, there is a poor consistency in the configurations of the stereogenic centers on the macrocycles; e.g., four diastereomers at $\mathrm{C6}^{\prime}$ and $\mathrm{C} 13^{\prime}$ are known as roridin E and its analogs [only epiisororidin $\mathrm{E}(\mathbf{2})$ is shown in Fig. 1]. ${ }^{16}$ As the configurations C4', C5', C6 ${ }^{\prime}$, and C13' of $\mathbf{1}$ were unknown, isolation of $\mathbf{1}$ allowed us to experimentally deduce them.

Prior to these investigations, the relative and absolute

configurations of the C1-C16 trichothecene moiety were experimentally confirmed. The NOESY spectrum afforded the correlations at $\mathrm{H} \alpha-3 / \mathrm{H}-4, \mathrm{H} \alpha-3 / \mathrm{H}-11, \mathrm{H}-4 / \mathrm{H}-11, \mathrm{H}-4 / \mathrm{H}-14, \mathrm{H}-4 / \mathrm{H}-15$, and $\mathrm{H} \beta-7 /$ $\mathrm{H}-13$, indicating that the relative stereochemistry of trichothecene part is identical to those of other roridins. ${ }^{11,17,18}$ The absolute configuration of this moiety was established by a chemical correlation with verrucarol (3) ${ }^{19,20}$ being obtained by a basic methanolysis of $\mathbf{1}$ as shown in Scheme 1. Crude sample $\mathbf{3}$ thus prepared ( 1.5 mg ) provided an ${ }^{1} \mathrm{H}$ NMR spectrum that showed accordance with the data in the literature; ${ }^{19}$ however, it was both qualitatively and quantitatively insufficient for measuring the specific rotation. It was found that the following derivatization into bis-O-2naphthoate 4 resulted in giving distinct Cotton effects at 242 $(\Delta \varepsilon+6.8)$ and $229 \mathrm{~nm}(\Delta \varepsilon-20.2)$ in the ECD spectrum after purification with preparative silica gel TLC. Fortunately, the producer fungus C. arbuscula afforded a considerable amount of 2, a congener carrying the same trichothecene unit. ${ }^{16}$ Basic methanolysis of $\mathbf{2}$ under the same abovementioned conditions afforded authentic $\mathbf{3}$ ( 4.5 mg ), which allowed us to obtain a reliable specific rotation
$\left([\alpha]_{D}^{22}-31.5\right.$ (c $\left.0.41, \mathrm{CHCl}_{3}\right)$ ). The following 2-naphthoylation afforded $\mathbf{4}$ ç which gave identical ECD spectrum to that of the sample prepared from 1. Ishihara and Tadano synthesized verrucarol in an optically active form to report its specific rotation $\left([\alpha]_{\mathrm{D}}^{21}-40.6\left(\mathrm{c} 0.13, \mathrm{CHCl}_{3}\right)\right)^{19,20} \mathrm{~A}$ combination of these results established the absolute configuration for the trichothecene moiety in $\mathbf{1}$, despite the indirect manner.

The vicinal spin couplings ${ }^{3} J_{\mathrm{H}-7^{\prime} / \mathrm{H}-8^{\prime}}(15.0 \mathrm{~Hz})$ and ${ }^{3} \mathrm{~J}_{\mathrm{H}-9^{\prime} / \mathrm{H}-10^{\prime}}$ ( 11.1 Hz ) confirm the same ( $7^{\prime} E, 9^{\prime} Z$ ) form as Jarvis's assignment. The NOESY spectrum affords a correlation between $\mathrm{H}-\mathrm{7}^{\prime}$ and $\mathrm{H}-9^{\prime}$, suggesting a transoid conformation for the $\mathrm{C} 7^{\prime}-\mathrm{C} 10^{\prime}$ diene moiety as shown in Fig. 3. In addition, NOESY correlations are found at H$4^{\prime} / \mathrm{H}-13^{\prime}$ and $\mathrm{H}-5^{\prime} / \mathrm{H}-6^{\prime}$, establishing a rel-( $\left.5^{\prime} R, 6^{\prime} \mathrm{S}, 13^{\prime} S\right)$ configuration of the 1,3-dioxolane ring moiety on the macrocycle.

The remaining structural unknowns were the absolute configurations of $\mathrm{C} 4^{\prime}$ and $\mathrm{C} 5^{\prime}$, which were investigated with the stable conformation, theoretical ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ chemical shifts, and ECD spectrum based on DFT $\omega$ B97X-D/6-31G* (structural optimization and chemical shift calculations) and BHLYP/def2-TZVP// $\omega$ B97X-D/ 6-31G* (ECD spectral calculations) by using a protocol similar to that used in previous studies. ${ }^{21,22}$ Since the macrocyclic part of $\mathbf{1}$ has high conformational flexibility, the conformational distribution was estimated based on the free energy $(G)$ by adding the entropic factor $(S)$ and the temperature term ( 298 K ) to the steric energy $(H)$. The $\delta_{\mathrm{C}}$ and $\delta_{\mathrm{H}}$ root-mean-square (RMS) values of each isomer were obtained from the residuals between the experimental and theoretical chemical shifts. As we have established the rel-( $\left.5^{\prime} R, 6^{\prime} S, 13^{\prime} S\right)$ configuration and the ( $2^{\prime} E, 7^{\prime} E, 9^{\prime} Z$ ) geometry via NMR analysis, the ( $4^{\prime} R$ ) and ( $4^{\prime} S$ ) epimers of both ( $2^{\prime} E, 5^{\prime} R, 6^{\prime} S, 7^{\prime} E, 9^{\prime} Z, 13^{\prime} S$ ) and ( $2^{\prime} E, 5^{\prime} S, 6^{\prime} R, 7^{\prime} E, 9^{\prime} Z, 13^{\prime} R$ ) forms (in total, four isomeric models) were subjected to the calculations. The models are expressed using three letters, e.g., ERR, and these three letters refer to the configurations at the $2^{\prime}, 3^{\prime}$ double bond, the $4^{\prime}$, and $5^{\prime}$ asymmetric carbons.

The calculations naturally revealed the stable conformers as shown in Fig. 4. First, we analyzed the transannular NOEs based on their stable conformers suggested by these calculations. Roridin J (1) shows transannular NOEs at $\mathrm{H}_{3}-14 / \mathrm{H}-2^{\prime}, \mathrm{H}_{3}-14 / \mathrm{H}-8^{\prime}, \mathrm{H}-2^{\prime} / \mathrm{H}-8^{\prime}$, and $\mathrm{H}-4 \mathrm{\prime} / \mathrm{H}-13$ '. The most stable conformer of model ERR explains all these NOEs. Since C4'-epimeric model ESR adopts the similar conformation on the basis of these calculations, this isomer would also satisfy most of the above NOEs; however, the distance between H-4' and H-13' (3.6 $\AA$ ) is slightly large to expect a distinct NOE between those (note that the distance between the vicinal transdiaxial protons on a chair formed cyclohexane is around $3.1 \AA$ ). The calculations also revealed that the $\mathrm{C1}^{\prime}-\mathrm{C} 4^{\prime}$-conjugated planes in the stable conformers of models ERS and ESS are flipped around from that in model ERR, which increased the distance between $\mathrm{H}_{3}$ 14 and $\mathrm{H}-2^{\prime}$ (ERS: $4.2 \AA$ and ESS: $4.0 \AA$ ). Thus, the NOE between these protons cannot be expected in those models. The
