A B S T R A C T

A series of Ag catalysts supported on γ -Al₂O₃, including two different γ -Al₂O₃ supports and various Ag loadings (2–8 wt.%), was prepared, characterized (SEM, TEM, BET, physisorption, TPR, NH₃-TPD) and tested for the selective catalytic reduction of NO_x by CH₄ for lean-burn natural gas engines exhausts. The catalysts containing 2 wt.% Ag supported on γ -Al₂O₃ were found to be most efficient for the NO_x reduction into N₂ with a maximal conversion of 23% at 650 °C. This activity was clearly linked with the ability of the catalyst to concomitantly produce CO, via the methane steam reforming, and NO₂. The presence of small AgOx nanoparticles seems to be crucial for the methane activation and NO_x reduction. 24

28 1. Introduction

30
31 Natural gas, mainly composed of methane, is one of the cleanest
32 burning hydrocarbon fuels. Due to its high carbon to hydrogen ratio,
33 the CO₂ emissions per unit of produced energy are limited. This prop-
34 erty, combined with the worldwide abundance of natural gas reserves,
35 makes it an appealing alternative fuel [1–3]. The utilization of natural
36 gas as a fuel in the transportation sector can partially substitute diesel
37 powered heavy-duty vehicles. Several studies have shown that natural
38 gas engines present reduced particulate matter (PM) emissions com-
39 pared to diesel engines, associated with a slight decrease in the CO₂
40 emissions [4, 5]. Therefore, the development of natural gas heavy-duty
41 vehicles can contribute to the decrease of the PM emissions in urban
42 areas and is a powerful strategy to decrease CO₂ and pollutant emis-
43 sions. However, this technology must keep with the Euro VI emission
44 legislations, applicable from September 2014, which limit the NO_x
45 emission level below 0.46 g/kWh for heavy-duty vehicles using natural
46 gas as a fuel. Therefore, an effective catalytic post-treatment is required
47 to reduce the emissions of unburnt CH₄, CO and NO_x. The selective cat-
48 alytic reduction of NO_x by urea (urea-SCR) can be efficiently imple-
49 mented using noble-metal free catalysts [6]. Even if the urea-SCR
50 requires an additional tank of urea and a controlled injection and de-
51 composition of urea, this technology is now commonly developed for
52 heavy-duty vehicles. Nevertheless, the corrosion and leakage of ammo-
53 nia are still problematic. A more straightforward and economical ap-
54 proach is to directly reduce NO_x with unburnt methane contained in

the exhaust. The selective catalytic reduction of NO_x by CH₄ (CH₄-
55 SCR) could remove simultaneously CH₄ and NO_x but is quite challeng-
56 ing and up to date there is no technology available. Noble metal-based
57 catalysts supported mainly on zeolites, alumina or zirconia have been
58 investigated for CH₄-SCR in the presence of oxygen [7–12]. Re-
59 cently, a synergic effect was reported by using a bimetallic Pd–Pt sup-
60 ported on sulfated zirconia. A bi-functional mechanism was proposed
61 with the NO oxidation to NO₂ occurring on Pt and coupled with the re-
62 duction of NO₂ by CH₄ on Pd [13]. However, the balance between the
63 PGM cost, their performance and durability are still insufficient for prac-
64 tical applications. 65

Alternative materials could be the Ag-based catalysts especially at
66 higher reaction temperatures [14, 15] and in the presence of water
67 [16–18]. In addition, the selectivity to N₂ over Ag-based catalytic sys-
68 tems is relatively high, leading to inexpensive materials, which are
69 more attractive compared to noble metal catalysts [19]. Many studies
70 have been performed on silver supported γ -alumina catalysts but 71

Table 1
Main properties of Ag/Al₂O₃ catalysts.

Sample	BET surface area (m ² g ⁻¹)	Ag content (wt.%)	Pore diameter (nm)	Pore volume (cm ³ /g)	Acidity (μmol NH ₃ · m ⁻²)	
Al ₂ O ₃ C	150	–	7	0.35	0.83	t1.4
Al ₂ O ₃ P	203	–	5	0.33	0.69	t1.5
2AgC	154	1.95	7	0.35	0.73	t1.6

mainly by using alkenes as reducing agents [20–25]. Only few studies are dealing with CH₄-SCR on Ag supported γ -Al₂O₃ systems in the literature [26–29]. The competition between the reduction of NO_x with methane and the methane combustion is driving the catalytic performances [30]. The nature of Ag species is the most crucial parameter affecting the catalytic performance for CH₄-SCR [14, 18, 20, 26, 29]. According to the literature data, silver oxide species finely dispersed on γ -Al₂O₃ seem to be the most active site for CH₄-SCR while metallic silver particles or Ag_n⁰ clusters lead to the methane combustion.

The objective of this study is to investigate the catalytic performances of Ag supported γ -Al₂O₃ catalysts for the CH₄-SCR of NO_x by using operating conditions comparable to those encountered in lean-burn natural gas engine exhausts. A series of catalysts, including two different γ -Al₂O₃ supports and various loadings of Ag, has been synthesized and characterized using several techniques (SEM, TEM, BET, physisorption, TPR, NH₃-TPD). The catalytic performance for the CH₄-SCR of NO_x was monitored as a function of temperature, partial pressures of methane and H₂O.

2. Experimental

2.1. Catalyst preparation

Two different γ -alumina supports have been used to disperse the Ag nanoparticles. The first one was prepared by the precipitation method (denoted as Al₂O₃P) from an aqueous solution 1 M of aluminum nitrate, Al(NO₃)₃·9H₂O (Sigma-Aldrich) at pH of ca. 9.0–10, controlled by addition of a NH₄OH (Sigma-Aldrich) solution 0.5 M. The precipitated Al(OH)₃ was washed three successive times with distilled water to remove nitrate and ammonium ions. The sample was dried at 110 °C overnight and then calcined in air at 700 °C for 6 h. This temperature was selected because this is the highest one encountered in a lean-burn natural gas engine exhaust.

The second support was a porous powder provided by PYLOTE (denoted as Al₂O₃C). The Ag/ γ -Al₂O₃ catalysts containing different Ag loadings were prepared by the wet impregnation method from an aqueous solution of AgNO₃ (Sigma-Aldrich). All catalysts have been dried at 110 °C for one night and then calcined in air at 700 °C for 6 h. Table 1 gives the list of investigated catalysts with their specific code.

2.2. Characterization of the catalysts

The Ag loading in the catalysts after the calcination step at 700 °C was measured by using the inductively coupled plasma atom emission spectroscopy. Nitrogen adsorption isotherms of the samples were measured at –196 °C (77 K) with a Tristar 3000 volumetric sorption analyzer. Prior to measurement, the samples (ca. 200 mg) were outgassed at 250 °C under vacuum. The specific surface area was calculated from the resulting isotherms using the BET method.

Scanning electron microscopy (SEM) was performed using a JEOL JSM 5800LV SEM electron microscope linked to an energy-dispersive

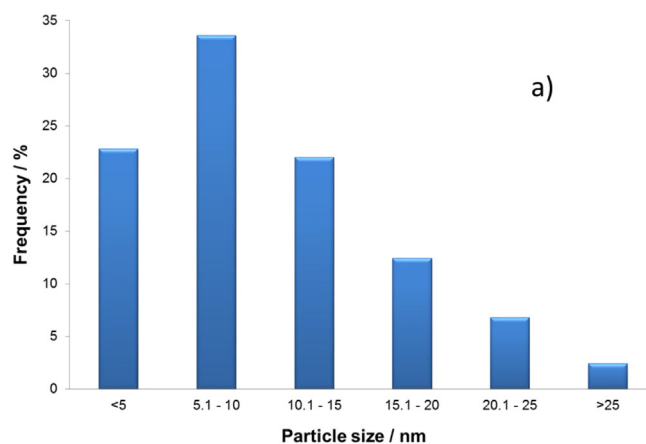

Fig. 2. TEM photograph (a) and particle size distribution (b) of 2AgP catalyst.

X-ray spectrometer (EDX) equipped with a SiLi diode (PGT). The samples were deposited onto a scotch carbon and metalized by sputtering. A gold film ensures a good conductivity for the observations.

Transmission electron microscopy (TEM, JEOL 2010 LaB6) was used to determine the morphology of the solid and the silver particle size distribution. The mean diameter was calculated using Eq. (1).

$$D = \frac{\sum NiDi}{\sum Ni} \quad (1)$$

where Ni is the number of Ag particles with a diameter Di. The ImageJ 1.44 software was used to measure Ag nanoparticle size from at least 10 TEM images and 250 nanoparticles.

Temperature programmed reduction (TPR) measurements have been performed in a U-shaped quartz catalytic reactor. An appropriate
