ABSTRACT

The discovery of new hydrogen storage materials has greatly driven the entire hydrogen storage technology forward in the past decades. Magnesium hydride, which has a high hydrogen capacity and low cost, has been considered as one of the most promising candidates for hydrogen storage. Unfortunately, extensive efforts are still needed to better improve its hydrogen storage performance, since MgH₂ suffers from high operation temperature, poor dehydrogenation kinetic, and unsatisfactory thermal management. In this paper, we present an overview of recent progress in improving the hydrogenation/de-hydrogenation performance of MgH₂, with special emphases on the additive-enhanced MgH₂ composites. Other widely used strategies (e. g. alloying, nanoscaling, nanoconfinement) in tuning the kinetics and thermodynamics of MgH₂ are also presented. A realistic perspective regarding to the challenges and opportunities for further researches in MgH₂ is proposed.

1. Introduction

What hampers our step towards a hydrogen-based energy system? Although plenty of issues, such as hydrogen generation, hydrogen transportation, hydrogen application, must be solved in our way to fulfil the worldwide commercial usage of hydrogen, it is the lack of ideal hydrogen storage material that primarily blocks the progress of hydrogen technology. The discovery of each novel hydrogen storage material (alloys, carbon materials, metal organic frameworks (MOFs), organic liquids, metal alanates, metal hydrides et al. [1–7]) had greatly promoted the revolution of hydrogen storage technology.

An ideal hydrogen storage material should meet the following standards: (1) cost-affordable, (2) high hydrogen storage capacity (5.5 wt% and 40 g L⁻¹ hydrogen capacity by 2020, U.S. Department of Energy [8]), (3) mild operation temperature and easy to absorb/de-absorb hydrogen, (4) long life-span. Fig. 1 showed some typical hydrogen storage technologies and compared their operation conditions [9]. Apparently, amongst all these strategies, metal hydrides exhibit huge potential for commercial storage of hydrogen. Especially, MgH₂ has been considered as one of the most promising candidates, due to its high hydrogen storage capacity (7.6 wt%, 110 g L⁻¹ H₂), abundance in deposit, and low cost.

MgH₂ is an ionic compound and its charge distribution is

Mg^{1.91+}H^{0.26-}. This structure results a high thermodynamic stability of MgH₂, which shows an enthalpy value of 74.7 kJ mol⁻¹, and an entropy value of 130 J K⁻¹ mol⁻¹. The high stability of MgH₂ leading to a high operation temperature (> 350 °C) which is not good for practical application. Another drawback of MgH₂ is its sluggish sorption kinetics, causing by the following reasons: (1) existence of oxide on its surface, (2) slow diffusion rate of hydrogen in the bulk MgH₂/Mg, (3) poor decomposition of hydrogen on the Mg surface [10]. Additionally, the unsatisfactory heat management of MgH₂/Mg also affects its hydrogenation/de-hydrogenation behaviours. All these problems above have hampered the worldwide application of MgH₂/Mg. To date, numerous efforts have been carried out to overcome these disadvantages, and huge improvements have been achieved. For example, Xia et al. synthesized monodisperse MgH₂ nanoparticles (NPs) that anchored on graphene sheet, and confirmed its impressive hydrogen storage properties, which released 5.4 wt% hydrogen within 30 min and showed an ultra-long cycle-life of 100 times [11].

In this paper, we summarized a wide range of promising strategies to tuning the hydrogen storage performance of MgH₂/Mg, with special focus on the advantages and challenges of each method. To better present the research progress of MgH₂/Mg, we classified the technologies into four categories: alloying, nanoscaling, nanoconfinement, and additive-addition. Rather than detail all outcomes of each classic

method, we pay especial attention on the additive-enhanced MgH₂ systems. By reviewing these data, we hope this paper can help more researchers better understanding MgH₂, and shed light on further works.

2. Overview of tuning strategies

The hydrogenation/de-hydrogenation process of MgH₂/Mg is illustrated in Fig. 2. Apparently, decreasing the energy barrier and/or changing the reaction enthalpy of MgH₂/Mg are fundamental ways to improve its hydrogen storage performance.

2.1. Alloying

One of the most effective methods to reduce the thermodynamic barrier of MgH₂/Mg is alloying. Instead of direct reaction between MgH₂ and Mg, the formation of Mg-alloys changes its sorption path. By forming thermodynamic more stable alloys, the operation temperature of MgH₂/Mg can be reduced. Various elements had been used to alloy with Mg, including rare earth elements, transition metals, and partial main group elements [12–24]. Table 1 summarizes the basic properties of some commonly investigated Mg-based hydrogen storage alloys.

Mg₂NiH₄, which has a lower enthalpy of 64 kJ mol⁻¹, is one of the most investigated Mg-alloys [37–39]. Kumar et al. reported that the hydrogen sorption of nanocrystalline Mg₂NiH₄ alloy started at 200 °C. However, the Mg₂NiH₄ alloy exhibited a low hydrogen capacity of only 3.6 wt%. Meanwhile, Mg₂FeH₆, which has a higher theoretical hydrogen capacity of 5.5 wt%, shows an even high enthalpy of 95 kJ mol⁻¹ H₂[40–43]. Chen et al. reported the hydrogen storage performance of

Mg₂FeH₆@MgH₂ core-shell, which released 5.0 wt% hydrogen within 50 min at 280 °C [14]. In 2012, Liu et al. reported the hydrogen storage properties of Mg@Mg₁₇Al₁₂ particles, which delivered 6.0 wt% hydrogen with 30 min at 350 °C, and absorbed 7.0 wt% hydrogen at 400 °C [44]. As shown in Fig. 3, the Mg₁₇Al₁₂ shell enclosed Mg core and effectively resisted the formation of MgO. The shell grown with the increased content of Al, but over high Al content would broke this core-shell structure.

Fig. 4 showed the de-hydrogenation/hydrogenation performance of LaMg₁₁Ni+x wt% Ni alloys [15]. Zhang et al. found that milling time and Ni content were both essential factors for enhancing the kinetics of LaMg₁₁Ni+x wt% Ni alloys. Good improvement was achieved for the LaMg₁₁Ni+200 wt% Ni sample, which absorbed 6.41 wt% hydrogen within 18 min, and reduced E_a to only 68.5 kJ mol⁻¹. Additionally, the Mg_{6–7}TMH_{12–16} (TM=Ti, Zr, Hf, V, Nb), which have a similar structure with CaF₂, also gained huge attention. The Mg_{6–7}TiH_{12–16} releases 4.7 wt% hydrogen at 330 °C, but its re-hydrogenation process is rather tough.

Generally, Mg-base hydrogen storage alloys can effective decrease the operation temperature, but the introduction of heavy metals also result a decreased hydrogen capacity in the system, and most of these Mg-base alloys still suffered from poor reversibility. Detail information about these Mg-based hydrogen storage alloys can refer to a recent review [24].

2.2. Nanoscaling

Nanoscaling has proven its possibility in optimizing the thermodynamics and kinetics of MgH₂. Theoretical calculation (based on the first principle theory) has predict that when reducing the grain size of
