## ABSTRACT

Amphetamine-related drugs, such as 3,4-methylenedioxymethamphetamine (MDMA) and methamphetamine (METH), are popular recreational psychostimulants. Several preclinical studies have demonstrated that, besides having the potential for abuse, amphetamine-related drugs may also elicit neurotoxic and neuroinflammatory effects. The neurotoxic potentials of MDMA and METH to dopaminergic and serotonergic neurons have been clearly demonstrated in both rodents and non-human primates. This review summarizes the species-specific cellular and molecular mechanisms involved in MDMA and METH-mediated neurotoxic and neuroinflammatory effects, along with the most important behavioral changes elicited by these substances in experimental animals and humans. Emphasis is placed on the neuropsychological and neurological consequences associated with the neuronal damage. Moreover, we point out the gap in our knowledge and the need for developing appropriate therapeutic strategies to manage the neurological problems associated with amphetamine-related drug abuse.

## 1. Dopamine neurotransmission and neuroinflammation

The primary brain targets for the damage induced by both 3,4-methylenedioxymethamphetamine (MDMA) and methamphetamine (METH) are the striatum and the substantia nigra (SN). Thus, dysregulation of nigro-striatal dopaminergic system is the major cause of motor impairments induced by these drugs of abuse. Moreover, inflammatory effects of MDMA and METH play a significant role in the eventual dopaminergic dysregulation and symptom manifestation by these drugs. Hence, we will present a short overview on dopamine (DA) transmission and receptors and the role of neuroinflammation in neurodegenerative diseases with particular focus on these two drugs.

MDMA and METH may act as indirect DA agonists, producing their effects through DA receptors. These receptors are coupled to heterotrimeric G proteins and are classified into two families: D<sub>1</sub>-like (which includes D<sub>1</sub> and D<sub>5</sub> receptors in mammals) and D<sub>2</sub>-like (which includes D<sub>2</sub>, D<sub>3</sub> and D<sub>4</sub> receptors) receptor families. Initially, these two families were defined functionally based on their ability to modulate adenylyl cyclase (AC) activity and cAMP accumulation in cells, but later this classification was confirmed by molecular cloning (Beaulieu and Gainetdinov, 2011). The D<sub>1</sub>-like receptors are found exclusively post-synaptically and activate the G<sub>as/olf</sub> family of G proteins to stimulate AC and cAMP production. The D<sub>2</sub>-like family are expressed both pre- and post-synaptically and activate the G<sub>ai/olf</sub> family of G proteins to inhibit AC and cAMP production (Beaulieu and Gainetdinov, 2011). There exist two variants of D<sub>2</sub> receptors: D<sub>2</sub>-short (D<sub>2</sub>-S) and D<sub>2</sub>-long (D<sub>2</sub>-L) (Giros et al., 1989; Monsma et al., 1989). The D<sub>2</sub>-S variant is expressed mostly pre-synaptically and is involved in autoreceptor functions (e.g. control of DA release and regulation of extrasynaptic DA levels), whereas D<sub>2</sub>-L is mainly a postsynaptic isoform (Usiello

et al., 2000; De Mei et al., 2009). In addition, D<sub>2</sub>-S potentiates DA transporter (DAT) activity via the formation of heteromeric protein–protein complexes with DAT localized in the dopaminergic terminals (Hadlock et al., 2010). Interestingly, the distribution of DA receptors is similar in humans and rodents (Ares-Santos et al., 2013).

The significance of DA receptors is reflected in the diverse action of DA in behavior and cognition, voluntary movement, motivation, punishment and reward, attention, learning and working memory (Granado et al., 2008a; Martín et al., 2008; Darmopil et al., 2009; Darvas and Palmiter, 2009, 2010; Ortiz et al., 2010; Murer and Moratalla, 2011; Espadas et al., 2012; Ruiz-DeDiego et al., 2015a,b). Moreover, DA receptors (e.g. D<sub>1</sub>-like receptors) may mediate the interactions between glutamatergic and dopaminergic systems (Rodrigues et al., 2007). Consistent with this broad spectrum of activities, there is a wide expression of DA receptors in the brain. Both D<sub>1</sub>-like and D<sub>2</sub>-like receptor subtypes are present in all of the known DA projection fields in the CNS and their expression generally overlaps in most brain areas. Moreover, D<sub>1</sub>-like and D<sub>2</sub>-like receptors are highly expressed in the striatum, nucleus accumbens, olfactory bulb, amygdala, frontal cortex and SN and, at lower levels, in the hippocampus and ventral tegmental area (VTA) (Moratalla et al., 1996a; Beaulieu and Gainetdinov, 2011; Gangarossa et al., 2012). The striatum, one of the areas most affected by MDMA and METH, is the site with the highest concentration of DA in the brain. Although multiple DA receptor subtypes are present in the striatum, the D<sub>1</sub>-like and D<sub>2</sub>-like receptors are the most abundant in this area. Interestingly, D<sub>1</sub>- and D<sub>2</sub>-containing projection neurons are segregated in the striatum, as well as in the nucleus accumbens (Callier et al., 2003; Beaulieu and Gainetdinov, 2011; Suárez et al., 2014). D<sub>1</sub> receptor is selectively expressed in striatal projection neurons that form
