A new method for the estimation of the completeness magnitude

C. Godano

Department of Mathematics and Physics, Second University of Naples, Caserta, Italy.

Abstract

The estimation of the magnitude of completeness m_c have strong consequences in any statistical analysis of seismic catalogue and in the evaluation of the seismic hazard. Here a new method for its estimation is presented. The goodness of the method has been tested using 10^4 simulated catalogues. Then the method has been applied to five experimental seismic catalogues: Greece, Italy, Japan, Northern California and Southern California.

Keywords: Completeness magnitude, Gutenberg-Richter distribution

1. Introduction

The magnitude of completeness m_c is defined as the lowest magnitude at which all the earthquakes, occurring in a certain region and in a given time window, are detected (Rydelek and Sacks 1989). The most important motivation to estimate this quantity is the direct impact on the evaluation of the Gutenberg-Richter (GR) distribution parameters: the scaling exponent b and the overall seismicity rate a . The GR parameters are, in general, the basis of the seismic hazard studies (e.g., Cornell 1968; Wiemer et al. 2009) and of the earthquake forecast models (e.g., Wiemer and Schorlemmer 2007). Moreover a correct estimate of a and b is crucial to better understand the physics of the earth's crust (e.g., Mignan 2011). In practice, a relatively high magnitude threshold may provide a conservative estimate of m_c but would deprive the dataset of potentially valuable information. On the contrary, a too small value of m_c will reflect in an incorrect estimate of the b value leading to wrong evaluations of the seismic hazard. Moreover, an incorrect estimate of m_c have strong consequences in any other further statistical analysis of the considered catalogue.
