Mesenchymal stem cells

Hematopoietic niche

ABSTRACT

Bone physiology and stem cells were tightly intertwined with one another, both conceptually and experimentally, long before the current explosion of interest in stem cells and so-called regenerative medicine. Bone is home to the two best known and best characterized systems of postnatal stem cells, and it is the only organ in which two stem cells and their dependent lineages coordinate the overall adaptive responses of two major physiological systems. All along, the nature and the evolutionary significance of the interplay of bone and hematopoiesis have remained a major scientific challenge, but also allowed for some of the most spectacular developments in cell biology-based medicine, such as hematopoietic stem cell transplantation. This question recurs in novel forms at multiple turning points over time: today, it finds in the biology of the “niche” its popular phrasing. Entirely new avenues of investigation emerge as a new view of bone in physiology and medicine is progressively established. Looking at bone and stem cells in a historical perspective provides a unique case study to highlight the general evolution of science in biomedicine since the end of World War II to the present day. A paradigm shift in science and in its relation to society and policies occurred in the second half of the XXth century, with major implications thereof for health, industry, drug development, market and society. Current interest in stem cells in bone as in other fields is intertwined with that shift. New opportunities and also new challenges arise. **This article is part of a Special Issue entitled “Stem cells and bone”.**

Introduction

Bone morphogenetic proteins, hematopoietic “niche,” and “mesenchymal” stem cells represent three totemic achievements in bone biology during the last century, three of the most research-intensive areas of the last three decades, and three of the most “translation”-intensive

research areas of the present day. The three fields emerged from an unusual concentration in space and time of a handful of seminal experimental observations. In just a few years, we learned that heterotopic transplantation of transitional epithelium into skeletal muscle induces heterotopic bone formation [1]; that heterotopic transplants of bone marrow also do so [2,3], but that the two phenomena are radically distinct from one another: the former is dependent on the release of a soluble factor, while the latter is not. Identification of BMPs [4–6,7] and perisinusoidal reticular cells as the specific factor and cell type

generating bone in heterotopic transplants of transitional epithelium and bone marrow, respectively, represents the ending point of two long and diverging journeys that originated from those seminal experiments. Likewise, the definition of the bone marrow microenvironment as the host of signals provided by stromal cells and required for hematopoiesis, and the pursuit of a “niche” for hematopoietic stem cells properly represent the developments over time of a third seminal observation; that is, that grafting of bone marrow in closed systems (diffusion chambers) would generate bone but bar the development of hematopoiesis, whereas transplantation in open systems would allow for both bone formation and development of marrow [2].

That all of these fundamental observations, which not only withstood the test of time, but also represented the seed for the subsequent flourishing of major fields of investigation, arose from the practice of heterotopic transplantation cannot escape notice. Considering the tremendous impact of establishing quail–chick chimeras (a kind of heterotopic transplantation in embryos) [8,9] in developmental biology and how much it contributed to further developments in lineage tracing, one is tempted by foolishly wondering what magic is inherent in putting tissues and cells where they do not belong (ectopic transplantation), and why is this practice so instructive. Perhaps all these simply highlight the fundamental link between space (and time) and development (lineage, commitment, differentiation), a notion we owe, ultimately, to Alan Turing (the father, among many other things, of the diffusion–reaction model which established the chemical basis of morphogenesis [10]), and before him, to D’Arcy Thompson (a classicist and a morphologist renowned for his attention to the physical and mathematical laws underpinning morphogenesis) [11]. Heterotopic transplantation is instructive because it breaks the spatial and temporal constraints (the physics, one could naively argue) that drive development, and therefore reveals them in the most empirical way possible.

99 The fallout: post-World War II era

100 That these fundamental observations clustered in a specific stretch
101 of time, on the other hand, is also intriguing. In the same, specific time
102 interval, another major change in scientific trends arose. The idea of a
103 hematopoietic stem cell, a common multipotent progenitor for all
104 blood cells, had been formulated long before (reviewed in [12]), but
105 had remained dormant without attracting interest and above all, exper-
106 imental effort. The idea exited the realm of theoretical postulates in
107 1961, with the seminal work of Till et al. [13,14], admittedly the first ex-
108 perimental evidence for a common multipotent progenitor of blood
109 cells. In essence, the fundamental discoveries of a dual system of stem
110 cells in bone were not only almost synchronous, but also arose from ef-
111 forts across the iron curtain that fell at the end of WWII, and are the di-
112 rect result of the way WWII ended. It was the attempt to develop
113 strategies for radioprotection that gave a new impetus to the science be-
114 hind what was to become stem cell biology. Not casually, the front page
115 of the famous New England Journal of Medicine paper by E. Donnall
116 Thomas reporting in 1957 [15] the first attempt of bone marrow trans-
117 plantation in humans both recounts the lethal effects of nuclear warfare,
118 and acknowledges the support of the Atomic Energy Commission of the
119 USA. Much more in bone science and science at large emanate from the
120 same cradle: the biology of bone matrix [16,17] and the role of parathy-
121 roid glands [18], for example, and key techniques such as microradiog-
122 raphy and autoradiography [16,17,19–21], to name a few.

123 At about the same time that something “osteogenic” was being
124 discovered in bone marrow by Tavassoli and Crosby [3], and by
125 Friedenstein and coworkers [2], it was exactly autoradiography that
126 made it possible to trace the kinetics of bone cells in vivo, in a series of
127 seminal studies by Owen and Macpherson [22–25]. This is how we
128 learned about precursor cells of osteoblasts in the inner layer of the peri-
129 osteum, about the origin of osteocytes from osteoblasts, and about the
130 kinetics thereof. Not casually, the two independent lines of thinking
131 about the origin and precursors of bone cells were to merge soon

132 thereafter in the work of Owen, just like her background in physics
133 and attention to biology had merged in her early work as a reflection
134 of the post-war climate and strategic priorities. Even the work of
135 Friedenstein and that of Owen united at one point [26], which was cru-
136 cial to disseminate the significance of Friedenstein’s work in the West
137 (Figs. 1 and 2). That unification was also crucial to formulate the concept
138 not only of a stem cell for bone, but also for different tissues together
139 comprising the skeleton being connected to one another at the level of
140 a common ancestor, rather than as separate entities as thought previ-
141 ously. For the first time, chondrocytes, osteoblasts and bone marrow ad-
142 ipocytes were brought together into a unified system. The “stromal
143 system” comprising them all was conceived on the blueprint of the
144 hematopoietic system, marking a major conceptual novelty in skeletal
145 research [26,27].

The road to stem cells

146
147 Earliest experiments provided evidence for an inherent osteogenic
148 potential of cells in bone marrow, and for its non-humoral nature. Sub-
149 sequent steps involved the use of cell culture as a way to separate, at a
150 time when no cell sorting tools were at hand, hematopoietic cells proper
151 from non-hematopoietic (stromal cells), which in contrast to the former
152 can adhere to a plastic substrate. Transplanting cultured stromal cells to
153 the effect of generating heterotopic bone proved that it was the stromal
154 fraction to be endowed with osteogenic potential. Using the same ex-
155 perimental approach, the same potential was later ascribed to the
156 clonogenic fraction of stromal cells (i.e., to cells capable of density-
157 insensitive clonal growth and therefore seen as progenitors), and to a
158 subset of individual clonogenic cells [28–30]. The coexistence of multi-
159 ple tissues within heterotopic “ossicles” generated by single clones
160 proved the existence, first in rodents and much later in humans [31],
161 of multipotent stromal progenitors, based on which the idea of an osteo-
162 genic stem cell was formulated as a working hypothesis [26,27,32].
163 Proving the existence of a bona fide stem cell also required proving
164 the ability of the multipotent progenitor to self-renew, but this key
165 question remained unaddressed for many years. Addressing this ques-
166 tion required the identification of an anatomical in vivo counterpart of
167 the multipotent clonogenic progenitor, and proof of its regeneration in
168 heterotopic transplants. This only came with the demonstration that:
169 a) the clonogenic fraction of bone marrow stromal cells in humans coin-
170 cides with perisinusoidal reticular cells; which b) could be pinpointed
171 using immunocytochemical markers both in the intact bone marrow
172 and in the heterotopic graft; and c) could be secondarily isolated from
173 the grafts, expanded and serially transplanted. First provided in humans
174 [33], this type of evidence was later provided in the mouse [34].
175 Completion of this pursuit over 40 years leaves us with the notions
176 that indeed, clonogenic, multipotent and self-renewing progenitors for
