97 Context

Top-down

ABSTRACT

Our first impression of others is highly influenced by their facial appearance. However, the perception and evaluation of faces is not only guided by internal features such as facial expressions, but also highly dependent on contextual information such as secondhand information (verbal descriptions) about the target person. To investigate the time course of contextual influences on cortical face processing, event-related brain potentials were investigated in response to neutral faces, which were preceded by brief verbal descriptions containing cues of affective valence (negative, neutral, positive) and self-reference (self-related vs. other-related). ERP analysis demonstrated that early and late stages of face processing are enhanced by negative and positive as well as self-relevant descriptions, although faces per se did not differ perceptually. Affective ratings of the faces comfirmed these findings. Altogether, these results demonstrate for the first time both on an electrocortical and behavioral level how contextual information modifies early visual perception in a top-down manner. 20

Introduction

What's in a face? This question has been raised many times since Darwin postulated that facial expressions are adaptive and important social 28 communicative signals (Darwin, 1872). Most of the research in cognitive 29 (neuro-)science so far has focused on single, static, context-less faces pos-30 ing high intensity levels of emotional expressions. Based on results from 31 32 these studies, it has been proposed that emotion recognition from faces is automatic, hard-wired, effortless and universal (Ekman, 1992), Howev-33 er, there is growing evidence now that faces do not always speak for 34 themselves, but their perception can be highly dependent on contextual 35 36 information (Barrett et al., 2011). As has been comprehensively reviewed recently, context cues may originate from within-face features such as eye 37 gaze and facial dynamics, within-sender features such as affective proso-38 39 dy and body posture, external features from the environment surrounding the face such as visual scene, other faces, social situations, and 40 within-perceiver features such as personality traits, affective learning pro-41 42 cesses and implicit processing biases (Wieser and Brosch, 2012).

Context clearly plays an even more important role when the emotion- 28 al information from a face is ambiguous such as in surprised faces (Kim 44 et al., 2004; Neta et al., 2011) or no emotional information is available 23 such as in neutral faces (Schwarz et al., 2013). The evaluation of ambigu- 46 ous faces is thought to be based on the two dimensions of valence and 47 dominance when there is no affective information available at all 48 (Todorov, 2011). However, when affective and other contextual variables 49 are available one may assume that these guide the face perception in their 50 direction. Indeed, previous encounters and the affective context can affect 51 early stages of face processing. For example, it was shown that faces pre- 52 viously set in a negative emotional context (gossip) afterwards dominate 53 in a binocular rivalry paradigm such that they gain perceptual dominance 54 (Anderson et al., 2011). Moreover, Morel et al. (2012) showed in a study 55 using magnet-encephalography (MEG) that faces previously paired only 56 once with negative or positive contextual information, are processed dif-57 ferently: The brain discriminates neutral faces between 30 and 60 ms 58 already post-face onset according to the type of emotional context previ- 59 ously associated with those faces. More precisely, the faces previously 60 seen in a positive (happy) emotional context evoked a dissociated neural 61 response as compared to those previously seen in either a negative 62 (angry) or a neutral context. Source localization showed that two main 63 brain regions were involved in this very early effect: the bilateral ventral, 64 occipito-temporal, extrastriate regions and right anterior medial temporal 65 regions. It is noteworthy to mention that in this study, the contextual 66 influences are based on previous encounters, but the contextual informa- 67 tion is not present at the time the face is seen again. 68

The same holds true for affective or social learning processes. In social conditioning paradigms it has been demonstrated that formerly neutral faces gain affective valence (as indexed by ratings) based on the social unconditioned stimulus (verbal description, voices with negative valence) they were paired with during an acquisition phase (Davis et al., 2010; lidaka et al., 2010). These effects were also accompanied by enhanced brain responses mainly in the amygdaloid complex underscoring the "new" affective valence and salience of previously neutral faces.

78 Important hints for the contextual modulation of brain responses to 79affective material come from studies in which preceding narratives were used to alter the meaning of subsequent neutral and emotional pic-80 tures (Foti and Hajcak, 2008; MacNamara et al., 2009, 2011). In these 81 82 studies it was demonstrated that the late positive potential (LPP) of the event-related brain potential which is thought as an index for sustained 83 perceptual processing is modified by picture-preceding narratives: The 84 amplitude of the LPP was reduced for both neutral and unpleasant pic-85 tures described neutrally as compared with unpleasant pictures described 86 negatively (Foti and Hajcak, 2008; MacNamara et al., 2009). Importantly, 87 these effects were observed to be enduring, as pictures previously preced-88 ed by negative compared to neutral narratives were rated as more 89 unpleasant and more emotionally arousing and elicited a larger LPP half 90 91 an hour after they were presented together with the context cues (MacNamara et al., 2011). This line of research shows that neural 92 responses to affective stimuli are effectively altered by preceding narra-93 tive contexts and suggests that context manipulations via verbal material 94may also change the electro-cortical processing of inherently neutral 9596 stimuli.

97 Besides explicit emotional contextual information another context variable is the self-reference of a given stimulus. As has been demonstrat-98 99 ed before, self-reference dramatically changes the perception of affective 100stimuli. For example, the cortical processing of affective words is 101 enhanced when self-reference is manipulated by a self-possessive pronoun (e.g., my pain vs. his pain, Herbert et al., 2011b). This is also reflected 102 in enhanced amygdala activity for pleasant words when related to the self 103 (Herbert et al., 2011a). Moreover, active emotion regulation conditions 104 105 during which participants self-evaluated their responses to emotional 106 stimuli compared to an evaluation of the emotional state of the central figure in the affective photo showed enhanced brain responses in 107 emotion-related brain areas (e.g., Ochsner et al., 2004). In this line of 108 research, the self-reference was manipulated to change or modify the 109 110 meaning of inherently affective stimuli, though. In contrast, a recent fMRI study demonstrated that even neutral stimuli (faces) rendered 111 self-relevant were associated with larger activity in frontal brain areas 112 (involved in self-referential processing), but also in sensory areas devoted 113 to face perception (fusiform gyrus) (Schwarz et al., 2013). Moreover, self-114 115relevant faces were also rated as more arousing and more emotional depending on the affective valence of the context. 116

These findings indicate that self-reference acts as a strong context 117 together with affective context variables in modulating both neural and 118 behavioral responses to neutral faces. Interestingly, not only brain areas 119 120 involved in self-referential processing, but also areas related to core face 121 perception such as the FFA were modulated. Taken together, selfreference has been demonstrated to alter processing of inherently affec-122tive stimuli, while modulations of the processing of neutral faces have 123been found by affective context variables given beforehand. The interac-124125tion of these variables on neutral face processing has been only investigated in one fMRI study, which precludes inferences about the stages at 126 which face processing is influenced by these context variables. While 127 early sensory processes in response to this kind of information have 128 been investigated either separately or with verbal material only, it has 129not been investigated yet when this information is integrated in the per-130ception of neutral stimuli when this information is given in advance. More 131 specifically, it remains unclear if this information is integrated at very 132early stages of face processing or if it is encoded separately and integrated 133 134 at later stages of visual processing.

In this light, event-related brain potentials (ERPs) are best suited for 135 investigating the time course of such influences and the integration of dif-136 ferent kinds of contextual information on face processing. Early ERP com- 137 ponent of interest are the occipital P100 and the face-specific occipito- 138 temporal N170. The P100 has been found to be modulated by facial 139 expressions (e.g., Wieser et al., 2012b), presumably reflecting enhanced 140 attention to emotional compared to neutral facial expressions. Further- 141 more, the N170 which is implicated in structural encoding of faces 142 (Bentin et al., 1996), is also presumably modified by their emotional con- 143 tent (for reviews, see Eimer, 2011; Vuilleumier and Righart, 2011), 144 although the empirical evidence for an emotional modulation of the 145 N170 is mixed and remains an issue of debate. Of greater relevance for 146 the current research questions are the subsequent emotion-sensitive 147 components such as the early posterior negativity (EPN), and the late pos-148 itive potential (LPP). Both of these are enhanced in response to emotional 149 faces (e.g., Mühlberger et al., 2009; Wieser et al., 2012a, 2012b), and index 150 relatively early (EPN) and sustained (LPP) motivated attention to salient 151 stimuli (Schupp et al., 2004; Wieser et al., 2010, 2012a, 2012b). As has 152 been mentioned above, the LPP is also strongly modulated by preceding 153 narratives which makes it a candidate component for the investigation 154 of the effects of preceding verbal context information on subsequent 155 face processing. Using this method, we sought to clarify at which stages 156 of stimulus processing affective contexts may alter face processing. 157 More specifically, we investigated whether these contexts already modify 158 early attentional brain responses and the structural encoding of faces and 159 whether possible modulations are relatively later at stages where normal- 160 ly emotional information is selectively processed, most likely due to influ- 161 ences stemming both from top-down and bottom-up bias signals. It is 162 important to note that EPN and LPP modulations are mostly found 163 when inherently affective stimuli are presented. In this study, however, 164 the potential emotional meaning only comes from the preceding 165 sentences and is not present at the time the face is presented. Modula- 166 tions of the face-evoked potentials would therefore demonstrate for the 167 first time that the brain also discriminates emotional meaning in faces 168 stemming from secondhand information. 169

Based on the literature as mentioned above, we aimed at elucidating 170 the time course of two contextual factors on face processing, namely 171 self-reference and contextual valence. Most importantly, the possible 172 interaction of both factors was a key target of the present study, as it 173 has not been investigated before whether self-reference and contextual 174 valence already interact on early levels of face processing. We hypothe- 175 sized that neutral faces put in an affective context by preceding brief ver- 176 bal descriptions would elicit stronger EPN and LPPs amplitudes compared 177 to faces put in neutral context. Moreover, we assumed that self-reference 178 would also enhance electro-cortical processing of neutral faces, and prob-179 ably even interact with contextual valence. Furthermore, we expected 180 these influences also to be present in affective ratings of neutral faces. 181 As the modulation of the P100 and N170 by facial expressions is inconsis- 182 tent, no clear a priori-hypotheses were formulated. However, both com- 183 ponents were analyzed to identify whether preceding contextual 184 information would alter early attentional processes as indexed by the oc- 185 cipital P100 or even the structural encoding of the faces (N170). If contex-186 tual modulation and particularly self-reference enhanced attention to 187 faces in general, one would expect larger P100 amplitudes for faces in 188 self-related compared to other-related contexts. If contexts altered struc- 189 tural encoding of faces, enhanced N170 amplitudes should be found. 190

Methods

Participants

Participants were 27 healthy adults (20 females) who received course 193 credits for participation. Two participants had to be excluded from data 194 analysis because of excessive eye movements and artifact-contaminated 195 EEG data (2 females). The remaining 25 participants were between 20 196 and 27 years of age (M = 22.4 years, SD = 5.12). The institutional review 197
