HIGHLIGHTS

- We examined the effect of repeated contingent opioid exposure on striatal medium spiny neurons (MSNs) in D1- and D2-GFP expressing mice.
- Mice were trained to self-administer remifentanyl, a mu opioid receptor agonist.
- Once stable self-administration was obtained, electrophysiology recordings were done.
- Mu receptors pre-synaptic to D1-, but not D2-, MSNs demonstrated reduced sensitivity.
- This finding suggests a specific adaptation of D1-MSNs after opiate self-administration.

ABSTRACT

Medium-sized spiny neurons (MSNs), the predominant neuronal population of the striatum, are an integral component of the many cortical and limbic pathways associated with reward-related behaviors. A differential role of the D1 receptor-enriched (D1) MSNs of the striatonigral direct pathway, as compared with the D2 receptor-enriched (D2) MSNs of the striatopallidal indirect pathway, in mediating the addictive behaviors associated with cocaine is beginning to emerge. However, whether opioids, well-known analgesics with euphoric properties, similarly induce dissociable signaling adaptations in these neurons remains unclear. Transgenic mice expressing green fluorescent protein (GFP)-labeled D1 or D2 neurons were implanted with intravenous jugular catheters. Mice learned to self-administer 0.1 mg/kg/infusion of the opioid remifentanyl during 2 h sessions over 13 contiguous days. Thereafter, the electrophysiological properties of D1- and D2-MSNs in the shell region of the nucleus accumbens (NAc) were assessed. We found that prior opioid exposure did not alter the basic membrane properties nor the kinetics or amplitude of miniature excitatory postsynaptic currents (mEPSCs). However, when challenged with the mu opioid receptor (μ OR) agonist DAMGO, the characteristic inhibitory profile of this receptor was altered. DAMGO inhibited the frequency of mEPSCs in D1-MSNs from control mice receiving saline and in D2-MSNs from mice exposed to remifentanyl or saline, but this inhibitory profile was reduced in D1-MSNs from mice receiving remifentanyl. Remifentanyl exposure also altered the probability of glutamate release onto D1-, but not D2-MSNs. Together these results suggest a D1-pathway specific effect associated with the acquisition of opioid-seeking behaviors.

Opioids are potent analgesics of important clinical value but can also induce euphoria. This can lead to abuse behaviors by those taking prescription opioids and contribute to the increasing diversion of these readily available pharmaceutical compounds for non-medical use [1]. As occasional opioid use transitions to habitual use, this progression is often accompanied by tolerance and dependence, which contribute to an escalating, prolonged pattern of opioid abuse. However, in contrast to our knowledge of the neuroadaptations induced by the traditional psychostimulants, much less is known of the adaptations of specific neural cells, and

¹ denotes equal contribution.

therefore circuits that mediate the transition from occasional to chronic opioid use and abuse.

The mesolimbic dopamine pathway is undoubtedly involved in the initial phase of opioid reward and reinforcement [2,3], with cooperative signaling through the D1 and D2 receptors expressed in striatal medium-sized spiny neurons (MSNs), mediating aspects of the unconditioned effects of the drug and subsequent conditioning [4–6]. As drug-taking progresses, the role of these receptors appears to diverge, with D2 receptor activation playing a more prominent role in cue-associated behaviors whereas the role of D1 receptors appears to diminish [7]; both receptors, however, appear to be involved in opioid-seeking after prolonged abstinence [8].

Though an understanding of the effects of psychostimulants on the neurophysiology of D1- and D2-enriched MSNs and their role in the initial psychomotor and reinforcing effects of psychostimulants is coming to light [9–12], there is little known of how prolonged voluntary opioid exposure alters these properties. To fill this gap, we have combined several techniques, including GFP-expressing mice, intravenous self-administration and electrophysiological recordings, to examine how the acquisition and maintenance of opioid-seeking behavior alters signaling properties of the D1-enriched, direct-pathway, and D2-enriched, indirect-pathway MSNs of the striatum.

Fully back-crossed male and female mice expressing D1- or D2-GFP [13] were bred from hemizygous mice crossed with C57Bl/6J mice to obtain hemizygous and wildtype littermates. Initially, both sexes were used to examine the effect of the GFP transgene on opioid sensitivity, which may alter cellular function and/or behavior. This was assessed by the studying the locomotor effect of an opioid agonist, fentanyl, which was used for these experiments as it is μ OR-specific and, unlike remifentanyl (according to pilot data not shown), induces a hyperlocomotion response. We found an effect of transgene insertion in female but not male mice (SFig. 1, Supplemental Information). Male D1- and D2-GFP mice were therefore used for the subsequent intravenous self-administration experiments and electrophysiological analyses.

An intravenous catheter (0.2 mm i.d., 0.4 mm o.d.; Cathcams, Oxford, UK) was implanted in the right jugular vein of male mice under sterile conditions as previously described [14]. After 7 days of recovery, and on a daily basis thereafter, mice were trained to self-administer remifentanyl (0.1 mg/kg/infusion) or had access to saline in operant conditioning chambers (Med-Associates Georgia, VT) in which the active versus inactive lever location was assigned in a counterbalanced manner across groups. Remifentanyl was chosen for these self-administration experiments as it is highly μ OR-specific and potent, has abuse-liability, and its short half-life facilitates the association of the active lever with the opioid infusion, thereby enhancing acquisition of self-administration behavior [15–17]. A response on the designated active, but not inactive, lever resulted in an intravenous drug infusion (0.67 μ l/g body weight), presentation of a 20 s visual cue and a 30 s 'timeout' period. The mice underwent a minimum of 10 days of acquisition training at Fixed Ratio 1 (FR1), followed by 3 to 4 days at Fixed Ratio 3 (FR3) where 1 or 3 lever presses respectively, resulted in an infusion, up to a maximum of 50 infusions/session. Self-administration behavior was considered established if a minimum of 20 infusions/session were obtained with no more than 30% variation in the number of infusions earned across the last 3 days.

Statistical Analysis: Over-dispersed count data gathered from self-administration sessions (counts of infusions earned and lever presses) were analyzed using Generalized Estimating Equations (GEE; see supplemental information) with a negative binomial distribution and a log link function along with an unstructured covariance matrix. Training day and lever (for analysis of active versus inactive pressing) were entered as repeated measures,

whereas genotype and self-administration drug were between-subjects factors.

Mice which had self-administered remifentanyl or saline were sacrificed 24 h after the last session for subsequent electrophysiological analysis. Slice preparation, cell identification, recording parameters and excitatory post-synaptic currents (EPSC) analysis were conducted as previously described [18,19]. Miniature EPSCs (mEPSCs) were recorded in the presence of tetrodotoxin (TTX, 1 μ M) and with or without DAMGO; [D-Ala², NMe-Phe⁴, Gly-o⁵]-enkephalin (1 μ M, 8–10 min).

Statistical Analysis: As there were no significant differences between labeled and non-labeled MSNs from the other genotype, data were pooled. High-frequency electrical noise was filtered in Clampfit and root mean square (rms) noise was calculated at 1–2 pA. Events with peak amplitudes between 10 and 50 pA were grouped, aligned by half-rise time, and normalized by peak amplitude. The effect of DAMGO was assessed during the last 2 min of application, the time of maximal effect [19]. Differences in average mEPSC amplitude and frequency between groups were analyzed with GEE using a gamma distribution and a log link function along with an exchangeable covariance structure and DAMGO application entered as a repeated factor. Amplitude-frequency histograms were also analyzed using the same GEE model, with amplitude bin and DAMGO application as repeated factors. Because many of these data equaled zero, a constant was added to all values to allow analysis with a gamma distribution (which best fit the data). Differences in inter-event interval (IEI) distributions, interpreted as probability of release, were analyzed using the Kolmogorov–Smirnov (KS) test.

We found that, when compared to saline mice (D1-GFP $n=4$, D2-GFP $n=5$), mice with contingent access to remifentanyl (D1-GFP $n=9$, D2-GFP $n=6$) acquired self-administration behavior and earned significantly more infusions at FR1 and FR3 schedules (both Wald $\chi^2 > 43.127$, p 's < 0.0001 , $df=1$, Fig. 1A). While no significant effects of or interactions with genotype were found for FR1 (all Wald $\chi^2 < 10.543$, p 's > 0.308), we did detect interactions with genotype during FR3 (day \times genotype: Wald $\chi^2 = 41.606$, $p < 0.001$, $df=2$; day \times drug \times genotype: Wald $\chi^2 = 39.191$, $p < 0.001$, $df=2$). However, pairwise comparisons between genotypes across FR3 days did not reveal any significant differences in infusions earned (remifentanyl mice: all p 's > 0.677 ; saline mice: all p 's > 0.246). As shown in Fig. 1B, mice self-administering remifentanyl learned to discriminate the active from inactive lever during FR1 (day \times lever: Wald $\chi^2 = 22.404$, $p = 0.008$, $df=9$) and maintained this discrimination during FR3 (lever: Wald $\chi^2 = 122.261$, $p < 0.001$, $df=1$; day \times lever: Wald $\chi^2 = 2.390$, $p = 0.303$, $df=2$), whereas saline mice did not (data not shown). Lever discrimination learning during FR1 and maintenance during FR3 did not differ as a function of genotype (all Wald $\chi^2 < 7.798$, p 's > 0.144 ; see supplemental information for further statistical analyses).

The basic cell membrane properties – capacitance (C_m), resting membrane potential (R_m), time constant or tau – were not different in D1- or D2-MSNs from mice receiving saline or remifentanyl. This indicates that chronic opioid self-administration did not produce major changes in MSN morphology or resting membrane potential (Table 1). There were also no dissociable effects of opioid self-administration on the amplitude, frequency or kinetics of spontaneous EPSCs in D1 and D2 neurons (data not shown).

As we have found that DAMGO inhibits miniature EPSC frequency in both types of MSNs in the NAc shell [19], we examined this effect following self-administration. We found that opioid self-administration specifically altered this profile in D1-MSNs (Fig. 2; cell type \times self-administration drug \times DAMGO application: Wald $\chi^2 = 4.251$, $p = 0.039$, $df=1$). Post hoc analysis, shown in Fig. 2A, demonstrated that DAMGO inhibited mEPSC frequency in both D1- and D2-MSNs from mice receiving saline (D1-MSNs: $p = 0.003$; D2-MSNs: $p = 0.040$). This inhibitory effect of DAMGO
