### Abstract

Advanced biosensors in future medicine hinge on the evolution of biomaterials. Porous silicon (pSi), a generally biodegradable and biocompatible material that can be fabricated to include environment-responsive optical characteristics, is an excellent candidate for *in vivo* biosensors. However, the feasibility of using this material as a subcutaneously implanted optical biosensor has never been demonstrated. Here, we investigated the stability and biocompatibility of a thermally-hydrocarbonised (THC) pSi optical rugate filter, and demonstrated its optical functionality *in vitro* and *in vivo*. We first compared pSi films with different surface chemistries and despite the outstanding stability of the THC pSi films, the material was found to be cytotoxic. We then showed that the cytotoxicity correlates with reactive oxygen species levels, which could be mitigated by pre-incubation of THC pSi (PITHC pSi). PITHC pSi facilitates normal cellular phenotypes and is biocompatible *in vivo*. Importantly, the material also possesses optical properties capable of responding to microenvironmental changes that are readable non-invasively in cell culture and subcutaneous settings. Collectively, we demonstrate, for the first time, that PITHC pSi rugate filters are both biocompatible and optically functional for lab-on-a-chip and subcutaneous biosensing scenarios. We believe that this study will deepen our understanding on cell-pSi interactions and foster the development of implantable biosensors.

**Keywords:** Silicon, Cytotoxicity, Biocompatibility, Biosensor, Biodegradation, Subcutaneous implant
