## ABSTRACT

Hierarchical TiO<sub>2</sub> hollow nanoboxes (TiO<sub>2</sub>-HNBs) assembled from TiO<sub>2</sub> nanosheets (TiO<sub>2</sub>-NSs) show improved photoreactivity when compared with the building blocks of discrete TiO<sub>2</sub>-NSs. However, TiO<sub>2</sub>-HNBs can only be excited by ultraviolet light. In this paper, visible-light-responsive N and S co-doped TiO<sub>2</sub>-HNBs were prepared by calcining the mixture of cubic TiOF<sub>2</sub> and methionine (C<sub>5</sub>H<sub>11</sub>NO<sub>2</sub>S), a N- and S-containing biomacromolecule. The effect of calcination temperature on the structure and performance of the TiO<sub>2</sub>-HNBs was systematically studied. It was found that methionine can prevent TiOF<sub>2</sub>-to-anatase TiO<sub>2</sub> phase transformation. Both N and S elements are doped into the lattice of TiO<sub>2</sub>-HNBs when the mixture of TiOF<sub>2</sub> and methionine undergoes calcination at 400 °C, which is responsible for the visible-light response. When compared with that of pure 400 °C-calcined TiO<sub>2</sub>-HNBs (T400), the photoreactivity of 400 °C-calcined methionine-modified TiO<sub>2</sub>-HNBs (TM400) improves 1.53 times in photocatalytic degradation of rhodamine-B dye under visible irradiation ( $\lambda > 420$  nm). The enhanced visible photoreactivity of methionine-modified TiO<sub>2</sub>-HNBs is also confirmed by photocatalytic oxidation of NO. The successful doping of N and S elements into the lattice of TiO<sub>2</sub>-HNBs, resulting in the improved light-harvesting ability and efficient separation of photo-generated electron-hole pairs, is responsible for the enhanced visible photocatalytic activity of methionine-modified TiO<sub>2</sub>-HNBs. The photoreactivity of methionine modified TiO<sub>2</sub>-HNBs remains nearly unchanged even after being recycled five times, indicating its promising use in practical applications.

## 1. Introduction

In the last 30 years, semiconductor photocatalysis has become an important research topic due to its potential applica-

tion in solving the problems of environmental pollution and energy crises, such as degradation of the organic pollutants [1–5], air purification [6–10], reduction of CO<sub>2</sub> to hydrocarbon fuel [11–13], and splitting water to produce hydrogen [14–17].

Among all the photocatalysts,  $\text{TiO}_2$  is the most studied because of its nontoxicity, higher chemical stability, and oxidizability features [18,19]. However, the wide band gap of anatase  $\text{TiO}_2$  (3.2 eV) hampers its wide practical application due to the fact that it absorbs only a very small ultraviolet part (3%–4%) of solar light [20,21]. To make use of the abundant amount of visible light (approximately 45%) from solar light, the development of visible-light-driven  $\text{TiO}_2$  is of great importance, but remains a great challenge [3,22,23]. Up to now, many strategies have been used to extend the light-responsive region of  $\text{TiO}_2$  from the ultraviolet (UV) to visible region, including dye sensitization [24,25], semiconductor coupling [17,26,27], doping  $\text{TiO}_2$  with metals or non-metals [22,28,29], noble-metal deposition [30], and surface-plasma effects [8,31,32]. Recent study also shows that modification of anatase  $\text{TiO}_2$  with graphene can also result in a visible-light response [33–35].

In recent years, hollow nanostructures have attracted much attention due to their unique properties and potential practical applications [36–39]. According to the literature, many hollow nanostructures have been prepared, such as nanotubes [40] and hollow micro/nanospheres [17,41–44]. Large fractions of void space in hollow structures have been successfully used to encapsulate and control release of sensitive materials such as drugs, cosmetics, and DNA [45]. Our group has previously reported the fabrication of  $\text{TiO}_2$  hollow nanoboxes ( $\text{TiO}_2$ -HNBs) assembled from  $\text{TiO}_2$  nanosheets ( $\text{TiO}_2$ -NSs) via a fluoride-induced self-transformation strategy by solvothermal treatment of cubic  $\text{TiOF}_2$  in alcohol solution [45]. It was found that the photoreactivity of the obtained  $\text{TiO}_2$ -HNBs under UV irradiation was improved when compared with that of the discrete building block  $\text{TiO}_2$ -NSs. Upon considering that  $\text{TiO}_2$ -HNBs can still only be excited by UV light, herein we prepared visible-light-responsive  $\text{TiO}_2$ -HNBs by *in situ* modification of  $\text{TiO}_2$ -HNBs with methionine ( $\text{C}_5\text{H}_{11}\text{NO}_2\text{S}$ ), a N- and S-containing biomacromolecule. We systematically studied the effect of calcination temperature on the structure and visible photocatalytic activity of methionine-modified  $\text{TiO}_2$ -HNBs.

## 2. Experimental

### 2.1. Synthesis

All reagents and solvents were of reagent grade (Wuhan Guoyao Chemical Co., China) and used without further purification.

Precursor  $\text{TiOF}_2$  nanocubes were synthesized by hydrothermal reaction. Briefly, 30 mL of acetate, 5 mL of hydrofluoric solution (40 wt%), and 15 mL of tetrabutyl titanate were mixed in a 100-mL PTFE beaker under magnetic stirring. The mixture was heated at 200 °C for 12 h in an autoclave. After cooling to room temperature, the resulting white powders were washed with water and ethanol several times and dried at 60 °C overnight.

To prepare methionine-modified  $\text{TiO}_2$ -HNBs, the mixture of 1.0 g of  $\text{TiOF}_2$  and 0.05 g of DL-methionine in a crucible was calcined at 400 °C for 2 h with a heating rate of 1 °C  $\text{min}^{-1}$ . Similarly, the mixture of  $\text{TiOF}_2$  and methionine was also calcined at

different temperatures, and the prepared sample denoted  $\text{TM}_x$ , where  $x$  represents the calcination temperature (300–500 °C). For example,  $\text{TM}_{400}$  means that the sample was prepared by calcining the mixture at 400 °C for 2 h.

In order to study the effect of methionine on the structure and performance of  $\text{TiO}_2$ -HNBs, direct calcination of  $\text{TiOF}_2$  in the absence of methionine was also performed under identical conditions, and the resulting sample denoted  $\text{T}_x$ , where  $x$  represents the calcination temperature (300–500 °C).

### 2.2. Characterization

The crystalline structure of the catalyst was characterized by powder X-ray diffraction (XRD) employing a scanning rate of 0.05°  $\text{s}^{-1}$  in a  $2\theta$  range from 10° to 60°, in a Bruker D8 Advance diffractometer using monochromatized  $\text{Cu } K_\alpha$  radiation. The morphology and microstructure of the as-prepared sample were analyzed by field-emission scanning electron microscopy (SEM) (Hitachi, Japan) and transmission electron microscopy (TEM) (G20, Tecnai, USA). Nitrogen adsorption-desorption isotherms were obtained from a nitrogen-adsorption instrument (ASAP 2020, USA), from which all the photocatalysts were degassed firstly at 150 °C, followed by investigating the surface areas and pore-size distribution of the photocatalysts. The UV-Vis diffused reflectance spectrum (DRS) was collected using a spectrophotometer (Shimadzu UV-2550, Japan) from 200 to 800 nm using  $\text{BaSO}_4$  as background. Fourier-transform infrared spectroscopy (FTIR) was recorded on a spectrometer (NEXUS 470) using the KBr pellet technique. X-ray photoelectron spectroscopy (XPS) spectra were recorded on a photoelectron spectrometer (VG Multilab 2000, VG, Inc., USA) using monochromatic  $\text{Al } K_\alpha$  radiation under vacuum at  $2 \times 10^{-6}$  Pa. All the binding energies were referenced to the C 1s peak at 284.8 eV of the surface adventitious carbon.

### 2.3. Measurement of the photocatalytic activity

The photocatalytic activity of the photocatalyst was evaluated both by photocatalytic decomposition of the organic dye rhodamine B (RhB) and NO oxidation under visible-light irradiation.

For RhB degradation, one cylindrical Pyrex® flask with a capacity of approximately 50 mL was used as the photoreactor vessel in the reaction system. Approximately 50 mg of the photocatalyst was put into 50 mL of RhB solution with a concentration of 1.0 g  $\text{L}^{-1}$ . After being ultrasonicated and stirred in the dark overnight to establish adsorption-desorption equilibrium, the solution was illuminated by an Xe lamp (300 W) with a cut-off filter ( $\lambda > 420$  nm). At given time intervals, 3.0 mL of suspension sample was taken and centrifuged to remove the photocatalyst particles. The concentration of the RhB in solution was monitored by UV-Vis spectroscopy at 554 nm.

NO oxidation was performed in a consecutive flow reactor at ambient temperature. The volume of the rectangular reactor constituted of stainless steel with a quartz glass cover was 4.5 L ( $L \times W \times H$ , 30.0 cm  $\times$  15.0 cm  $\times$  10.0 cm). A simulated visible-light source was acquired from an LED lamp ( $\lambda > 400$  nm).
