Cu<sup>+</sup> catalyst

## ABSTRACT

In this paper, we report photoelectrochemical (PEC) conversion of carbon dioxide (CO<sub>2</sub>) using photocathodes based on Cu<sub>2</sub>O nanowires (NWs) overcoated with Cu<sup>+</sup>-incorporated crystalline TiO<sub>2</sub> (TiO<sub>2</sub>-Cu<sup>+</sup>) shell. Cu<sub>2</sub>O NW photocathodes show remanent photocurrent of 5.3% after 30 min of PEC reduction of CO<sub>2</sub>. After coating Cu<sub>2</sub>O with TiO<sub>2</sub>-Cu<sup>+</sup> overlayer, the remanent photocurrent is 27.6%, which is an increase by 5.2 fold. The charge transfer resistance of Cu<sub>2</sub>O/TiO<sub>2</sub>-Cu<sup>+</sup> is 0.423 kΩ/cm<sup>2</sup>, whereas Cu<sub>2</sub>O photocathode shows resistivity of 0.781 kΩ/cm<sup>2</sup> under irradiation. Mott-Schottky analysis reveals that Cu<sup>+</sup> species embedded in TiO<sub>2</sub> layer is responsible for enhanced adsorption of CO<sub>2</sub> on TiO<sub>2</sub> surface, as evidenced by the decrease of capacitance in the Helmholtz layer. On account of these electrochemical and electronic effects by the Cu<sup>+</sup> species, the Faradaic efficiency (FE) of photocathodes reaches as high as 56.5% when TiO<sub>2</sub>-Cu<sup>+</sup> is added to Cu<sub>2</sub>O, showing drastic increase from 23.6% by bare Cu<sub>2</sub>O photocathodes.

## 1. Introduction

Growing concern over the ever-increasing level of carbon dioxide (CO<sub>2</sub>) in atmosphere has been strong impetus to search for solutions to mitigate the issue [1–3]. An ultimate formula for lowering CO<sub>2</sub> concentration would include conversion of CO<sub>2</sub> into chemicals that can be harnessed in a form of value-added product. For chemical conversion of CO<sub>2</sub>, various approaches have been proposed and investigated: heterogeneous catalysis, electrocatalysis, and bio-mitigation using microalgae, to name a few [4–9]. Yet, it requires high external energy (in the range of several tens to hundreds kJ/mol) to convert thermodynamically stable CO<sub>2</sub> (standard heat of formation for CO<sub>2</sub>, ΔH<sub>f</sub><sup>0</sup> = −393.51 kJ/mol) [10,11], demanding high temperature in gas-phase reactions [6–8] or large overpotential in electrochemical reactions [4]. In photocatalytic and photoelectrochemical (PEC) reduction of CO<sub>2</sub> into hydrocarbons (e.g., formic acid, methanol, or methane), sunlight serves as an energy source, hence increasing possibility of completely carbon-neutral energy production. Critical to the efficiency of the photocatalytic and photoelectrochemical conversion of CO<sub>2</sub> is to design structure of photocatalysts or photoelectrodes in such a way that (i) photogenerated charge carriers in semiconductors are

effectively utilized in the CO<sub>2</sub> reduction and (ii) catalytic surface lowers the energy of intermediate species as a result of controlled adsorption of CO<sub>2</sub> on the surface [12,13].

PEC reduction of CO<sub>2</sub> is an excellent test bed to quantify these effects; however, the poor stability of photoelectrodes and low Faradaic efficiency (FE) of overall system have posed major challenges.

Among all the semiconductors under investigation for developing efficient PEC CO<sub>2</sub> reduction, cuprous oxide (Cu<sub>2</sub>O) has been studied for the use in photocatalysis due to its low toxicity, high abundance and low processing cost compared with other p-type semiconductors [14–17]. In addition, Cu<sub>2</sub>O has narrow band gap energy (1.9–2.2 eV) to utilize sunlight and thermodynamically favorable energy band positions with the conduction band lying more negative of the CO<sub>2</sub> reduction potential [18]. Cu<sub>2</sub>O shows the theoretical maximum solar-to-fuel conversion efficiency 18% and maximum photocurrent density is calculated to be 14.7 mA/cm<sup>2</sup> [19]. However, photocurrents generated from PEC CO<sub>2</sub> reduction in reported studies have been much lower than the theoretical value, with the photocathodes exhibiting poor stability due to photocorrosion [16,20–22]. Photocorrosion is a common problem for narrow band gap semiconductors (i.e., E<sub>g</sub> < 2 eV) in an electrolyte solution since their self-reduction/oxidation potential levels lie between the conduction and valence band energy levels of semiconductors. The photocorrosion of semiconductors lowers the overall FE of PEC system since a large portion of the photo-generated charges are lost

by photocorrosion of  $\text{Cu}_2\text{O}$  and/or by the trapping process at the trap sites induced by photocorrosion [23]. Thus, the design and fabrication with high FE are important.

Several approaches have been reported in the way of increasing FE of photocathodes for  $\text{CO}_2$  reduction. Won et al. investigated the FE and selectivity of  $\text{Cu}_2\text{O}/\text{CuO}$  photocathodes by introducing various metal co-catalysts for methanol and formic acid production from  $\text{CO}_2$  [20]. To produce more valuable hydrocarbons such as methanol with high selectivity,  $\text{Cu}^+$  incorporation to  $\text{TiO}_2$  has been suggested as well. Liu et al. reported that  $\text{Cu}(\text{I})/\text{TiO}_{2-x}$  provides the active adsorption and reaction site of  $\text{CO}_2$  and also can spontaneously dissociate  $\text{CO}_2$  by in-situ FTIR analysis [24]. It is suggested that  $\text{Cu}^+$  state on  $\text{TiO}_2$  surface is the primary active site for photoreduction of  $\text{CO}_2$  and selectively produced methanol [25]. Slamet et al. also showed that Cu-doped  $\text{TiO}_2$  catalyst selectively produce methanol from  $\text{CO}_2$  [26]. In addition to the experimental proof, computational calculation revealed that selective methanol production from  $\text{CO}_2$  on  $\text{Cu}(\text{I})$  oxide nanolayers and clusters is favorable considering the binding and activation energy of intermediate species [10]. However, to the best of our knowledge,  $\text{Cu}^{+}$ -incorporated  $\text{TiO}_2$  has not been used as a protective overlayer of narrow band gap semiconductor and has not been applied to PEC  $\text{CO}_2$  reduction yet.

In this study, we examine  $\text{Cu}_2\text{O}$  nanowire (NW)-based photocathodes for PEC conversion of  $\text{CO}_2$ . Our primary focus lies on understanding what affects the FE of  $\text{Cu}_2\text{O}$ -based photocathodes during PEC reduction of  $\text{CO}_2$ . Various electrochemical analyses were performed in order to elucidate the characteristics of photo-generated charge carriers in  $\text{Cu}_2\text{O}$ -based photocathodes.

## 2. Experimental

### 2.1. Materials

The following chemicals were purchased from Sigma-Aldrich and used without additional treatment: copper(II) sulfate pentahydrate ( $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ ,  $\geq 99.99\%$ ), copper(II) chloride dihydrate ( $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ ,  $\geq 99.99\%$ ), potassium hydroxide ( $\text{KOH}$ ,  $\geq 85\%$ ), sodium hydroxide ( $\text{NaOH}$ ,  $\geq 97\%$ ), titanium butoxide (TOB, 97%), potassium bicarbonate ( $\text{KHCO}_3$ , 99.7%) and ethanol (anhydrous,  $\geq 99.5\%$ ).

### 2.2. Fabrication of photocathodes

Cu film was prepared by electrodeposition from saturated copper(II) sulfate pentahydrate ( $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ ) aqueous solution at 10 V for 20 s and 5 V for 150 s on fluorine-doped tin oxide (FTO) using a Pt counter electrode. After Cu deposition, the substrate was washed with deionized water ( $\text{DI-H}_2\text{O}$ ) and ethanol and then dried under air flow. The  $\text{Cu}(\text{OH})_2$  nanowires (NWs) were prepared by anodizing Cu coated FTO substrates at constant current density ( $10 \text{ mA}/\text{cm}^2$ ) at room temperature in 3 M  $\text{KOH}$  solution for 180 s and then washed with  $\text{DI-H}_2\text{O}$  and ethanol [14]. The  $\text{Cu}(\text{OH})_2$  NWs were transformed into  $\text{Cu}_2\text{O}$  NWs by thermal annealing at  $600^\circ\text{C}$  in Ar atmosphere for 4 h. The heating rate was  $30^\circ\text{C}/\text{min}$ .

Deposition method of amorphous  $\text{TiO}_2$  ( $a\text{-TiO}_2$ ) was slightly modified from the literature [27].  $a\text{-TiO}_2$  was deposited on  $\text{Cu}_2\text{O}$  NWs by dip coating. The precursor solution was 0.5 mL TOB in 20 mL anhydrous ethanol. The  $\text{Cu}_2\text{O}$  NWs were immersed into the solution for 1 min followed by air drying for 1 min. The dipping process was carried out five times. To crystallize  $a\text{-TiO}_2$ ,  $\text{Cu}_2\text{O}/a\text{-TiO}_2$  electrode was annealed in Ar atmosphere for 5 h at  $550^\circ\text{C}$ .

$\text{Cu}^+$  species was incorporated onto  $c\text{-TiO}_2$  surface by immersing a  $\text{Cu}_2\text{O}/\text{TiO}_2$  electrode in 3 mM  $\text{CuCl}_2$  in 0.25 M  $\text{NaOH}$ /ethanol solution. After 12 h, the electrode was washed with ethanol and annealed in Ar atmosphere for 1 h at  $300^\circ\text{C}$ . Finally, the samples were stored in an Ar-filled glove box.

### 2.3. Physicochemical characterization

Different types of photocathodes were characterized by field emission scanning electron microscopy (SEM), field emission transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES) and X-ray diffraction (XRD). SEM measurements were performed with a NOVA230 (FEI). TEM measurements were performed with a Tecnai F20 (FEI) operated at an acceleration voltage of 200 kV. XPS and AES measurements were performed with a Sigma Probe (Thermo VG Scientific). XRD measurements were performed with an Ultima IV (RIGAKU) operated with a  $\text{CuK}\alpha$  source ( $\lambda = 1.54 \text{ \AA}$ ). The data was collected with a scan rate of  $3^\circ/\text{min}$  ranging from  $20^\circ$  to  $80^\circ$ .

### 2.4. PEC measurement

We conducted PEC reduction of  $\text{CO}_2$  in a three electrode configuration cell using Pt wire with glass tube and membrane as the counter electrode to prevent backward reaction on Pt electrode and  $\text{Ag}/\text{AgCl}$  (3 M  $\text{NaCl}$ ) as the reference electrode. The potential measured using a  $\text{Ag}/\text{AgCl}$  reference electrode has been converted to the reversible hydrogen electrode (RHE) using the following formula:

$$E_{\text{RHE}} = E_{\text{Ag}/\text{AgCl}} + 0.197 + 0.059 \text{ pH}$$

Different photocathodes with an exposed surface area of  $0.25 \text{ cm}^2$  were connected to custom-made Teflon reactor. An aqueous solution of  $\text{CO}_2$ -saturated 0.3 M  $\text{KHCO}_3$  (pH 6.8) was used as the electrolyte during the measurement. Linear sweep voltammetry (LSV) was carried out using a VERTEX potentiostat (Ivium Technologies) at a scan rate of  $50 \text{ mV}/\text{s}$  under a chopped illumination of  $100 \text{ mW}/\text{cm}^2$  (using LS 150 with AM1.5 G filter, Abet Technologies). We performed the stability test under chopped illumination with 1 min of time interval at 0.3 V (vs. RHE) for 30 min.

### 2.5. Impedance measurements

The electrochemical impedance measurements were carried out using the same experimental setup. The Nyquist plots were obtained in the dark and under AM1.5 G illumination at an applied potential of 0.3 V (vs. RHE) within the frequency range of 100 kHz–100 mHz using an amplitude of 10 mV. We also performed the Mott–Schottky experiments with the potential range of 0.3–0.8 V (vs. RHE) using three different frequencies of 15, 25, and 50 Hz.

## 3. Results and discussion

### 3.1. Structural characterization of $\text{Cu}_2\text{O}$ nanowires and $\text{TiO}_2\text{-Cu}^+$ overlayer

Fig. 1(a) shows the fabrication process of different photocathodes. First,  $\text{Cu}(\text{OH})_2$  NWs were transformed into crystalline  $\text{Cu}_2\text{O}$  NWs via thermal annealing at  $600^\circ\text{C}$  (Fig. 1(b)). After dip-coating in  $\text{TiO}_2$  precursor solution, thin layer of  $a\text{-TiO}_2$  was formed on the surface of  $\text{Cu}_2\text{O}$  NWs and TEM images are presented in Fig. S1 (Supplementary materials).  $a\text{-TiO}_2$  was transformed into crystalline anatase  $\text{TiO}_2$  ( $c\text{-TiO}_2$ ) by annealing at  $550^\circ\text{C}$  in Ar atmosphere. Crystal structure of  $\text{TiO}_2$  was confirmed to be anatase using both XRD and TEM analyses (Fig. 1). Because of the volume shrinkage of the  $a\text{-TiO}_2$  during crystallization [28], thickness of  $c\text{-TiO}_2$  shell was not as uniform as that of  $a\text{-TiO}_2$ , but the  $c\text{-TiO}_2$  shell also appear to coat entire  $\text{Cu}_2\text{O}$  surface (Fig. S1). After incorporation of Cu species, we did not notice change in SEM and TEM analysis, and also could
