A B S T R A C T

Bioethanol production is one pathway for crude oil reduction and environmental compliance. Bioethanol can be used as fuel with significant characteristics like high octane number, low cetane number and high heat of vaporization. Its main drawbacks are the corrosiveness, low flame luminosity, lower vapor pressure, miscibility with water, and toxicity to ecosystems. One crucial problem with bioethanol fuel is the availability of raw materials. The supply of feedstocks for bioethanol production can vary season to season and depends on geographic locations. Lignocellulosic biomass, such as forest-based woody materials, agricultural residues and municipal waste, is prominent feedstock for bioethanol cause of its high availability and low cost, even though the commercial production has still not been established. In addition, the supply and the attentive use of microbes render the bioethanol production process highly peculiar. Many conversion technologies and techniques for biomass-based ethanol production are under development and expected to be demonstrated. In this work a technological analysis of the biochemical method that can be used to produce bioethanol is carried out and a review of current trends and issues is conducted. Q2

75 1. Introduction

76 Nowadays, the depletion of fossil fuels and the environmental
77 compliance regarding the greenhouse gases has attracted the interest
78 in non-conventional fuel from bioresources [1,2,3,4,5]. For the past
79 few years, the biomass-based ethanol has caught the attention of
80 global industry. According to the Renewable Fuels Association [6],
81 United States (U.S.) and Brazil are the pioneer countries in global
82 bioethanol production with a percentage of approximately 90%. The
83 involvement of several countries has already begun in new pathway
84 development for biogasoline from biomass [7]. Wheals et al. [8] refer
85 that in North America, bioethanol is primarily provided from starch
86 sources (corn starch) while in South America is mostly extracted from
Q3 sugars (sugarcane juice) and molasses [8,9]. (See Tables 1–3.)

88 On the other side, the European countries focus on biodiesel and
89 biogasoline production which exceeds 50% of the global production
90 cause of engines development and feedstocks supply costs [10,11,12,
91 13,14]. Despite the fact that most of the countries in the world, China,
92 India and Japan continue to invest in technologies from agricultural
Q4 residues and appear as future producers [15,16,17,18,19]. Although
94 bioethanol based on corn and sugar is an encouraging replacement to
95 gasoline in transportation sector, the amount produced is insufficient
96 with respect to the annual consuming amount worldwide. There is no
97 black-and-white answer to the question of what constitutes the most
98 suitable feedstock for the bio-based economy. Generally, sugars, oils
99 and proteins can be used in many applications. The concern for the
100 food security has globally increased the interest of researchers to focus
101 on alternative feedstocks [20,21,22].

102 The nova Institute of Germany claims that lignocellulosic resources
103 are favorable in terms of environmental sustainability and food
104 security as they do not antagonize food crops and animal feed as
105 renewable substrate for bioethanol production [23,24]. Moreover, the
106 availability of lignocellulosic materials in industrial-scale basis is
107 increased cause of the exploitation of industrial wastes and agricultural
108 residues [25,26,27]. Lignocellulosic wastes are a promising feedstock
109 considering its availability and low cost. The utilization of corn stover,
110 rice, wheat and sugarcane bagasse is gaining significant importance
111 worldwide [28,29,30,31].

112 Nonetheless, the recalcitrant structure of lignocellulose requires
113 high capital cost processing. Therefore, these technologies are not
114 economically achievable [32,33]. During the decomposition of
115 lignocellulosic material, it must be considered that D-xylose is the
116 second important sugar which has to be broken down as is found in
117 high portion in the feedstock [34]. The conversion of biomass to
118 ethanol has 4 main steps: pretreatment, hydrolysis, fermentation and
119 distillation. During the last decades genetic engineering and enzymatic
120 processing have provided significant improvements in all of the four
121 steps of ethanol production and making capable to ferment different
122 sugars concurrently [35,36,37]. Even though there is a wide range of

bacteria, they cannot all be adapted to saccharification process 123
conditions and several bacteria produce low ethanol yields. For this 124
reason, subtle improvements are sometimes required [38]. 125

The microbial contamination is a crucial problem in bioethanol 126
production process. Bacterial infections occur during bioethanol 127
fermentation which consume nutrients necessary for the fermentation 128
itself and it is possible to produce toxic products too. Both of these 129
situations can negatively affect the bioethanol yield [39,40]. The 130
formation of inhibitory by-products during the biofuel production must 131
be taken into account. Pienkos and Zhang [41] refer that pretreatment 132
and conditioning processes release toxic compounds into the 133
hydrolysate which inhibit the bacteria growth and decrease the ethanol 134
yield. The mechanism/methodology applied for biomass pretreatment 135
influences the relevant toxicity rate [41,42]. This review examines 136
recent technologies and trends that are used in lignocellulosic 137
bioethanol production. It also provides a summary of the current 138
problems and barriers concerning the different pathways and analyses 139
potential issues and trends of biotechnological conversion performance. 140

141 2. Current status

In 2014, the global production of bioethanol reached 24.5 billion gal, 142
up from 23.4 billion gal in 2013 which shows the international 143
bioethanol market is at a very dynamic stage [43]. More than half 144
(about 60%) of global bioethanol production is based on sugar cane 145
conversion and the rest (40%) comes from other crops [44]. United 146
States and Brazil are the global producers as they produce more than 147
70% of the global bioethanol production. 148

Even the main source for bioethanol production is considered to be 149
the corn from US and sugar cane from Brazil, any country with 150
agro-industrial economy can be involved in bioethanol fermentation. 151
This is feasible cause of the current progress in bioconversion of 152
non-food crops in large scale production [46]. 153

In Europe the biochemical pathways show a crucial potential 154
for research development in conjunction with the progress in 155
biorefineries. It is important to clarify that several technologies are 156
under development such as the SSCF technology which gains space in 157
biotechnology research area. Research requires effort to solve problems 158
concerning process improvement and confront challenges regarding 159
the overall efficiency of a biorefinery [47]. It was also reported in 2009 160
that notwithstanding the global economic-constraints, bioethanol 161
production continues to increase and to support significantly to the 162
global development [48]. 163

164 3. Lignocellulosic sources and composition

165 3.1. Raw materials and characteristics

Sustainable biofuel production in Europe can be met with 166
lignocellulosic biomass usage [49]. There is a wide variety of raw 167
materials that are discerned by their makeup, structure and 168
process-ability. In North America most cultivated land comprises. 169

The land cultivation is mainly based on forestland (around 35%), 170
grazed land (27%) as well as crop lands (19%) which constitute 171
approximately 9.0 million km² [51,52,53]. Forest sources include 172
woody biomass consisting mainly of residues or by-products from 173
manufacturing processes, biomass plantations, agricultural residues 174
(trees and branches) [54,55]. Cellulose materials can also be collected 175
