## HIGHLIGHTS

► A tri-dimensional dynamic complex model of a parabolic-trough collector is proposed.

- ► The collector model was validated with experimental data and agrees very well.
- ► An innovative co-simulation integration environment for PTC plants is developed.
- ► Co-simulations with complex dynamic and simplified stationary models were compared.
- ► Co-simulations for a reference solar industrial process heat scenario are presented.

## ABSTRACT

In the present paper a tri-dimensional non-linear dynamic thermohydraulic model of a parabolic trough collector was developed in the high-level acausal object-oriented language Modelica and coupled to a solar industrial process heat plant modeled in TRNSYS. The integration is performed in an innovative co-simulation environment based on the TLK interconnect software connector middleware. A discrete Monte Carlo ray-tracing model was developed in SolTrace to compute the solar radiation heterogeneous local concentration ratio in the parabolic trough collector absorber outer surface. The obtained results show that the efficiency predicted by the model agrees well with experimental data with a root mean square error of 1.2%. The dynamic performance was validated with experimental data from the Acurex solar field, located at the Plataforma Solar de Almeria, South-East Spain, and presents a good agreement. An optimization of the IST collector mass flow rate was performed based on the minimization of an energy loss cost function showing an optimal mass flow rate of 0.22 kg/s m<sup>2</sup>. A parametric analysis showed the influence on collector efficiency of several design properties, such as the absorber emittance and absorptance. Different parabolic trough solar field model structures were compared showing that, from a thermal point of view, the one-dimensional model performs close to the bi-dimensional. Cosimulations conducted on a reference industrial process heat scenario on a South European climate show an annual solar fraction of 67% for a solar plant consisting on a solar field of 1000  $m^2$ , with thermal energy storage, coupled to a continuous industrial thermal demand of 100 kW.

#### 1. Introduction

Co-simulation is an innovative simulation concept that consists on coupling distributed parallel simulation tools in an integrated environment that manages the data flow and synchronization between them [1-3]. This modeling and simulation philosophy explores the synergies of combining different tools in a cooperative way, hence allowing the development of more complex overall models in a shorter time. In spite of these advantages there are still

\* Corresponding author. Tel.: +351 966341445. *E-mail address:* ricardosilva@ual.es (R. Silva). at present no known studies of co-simulation applied to parabolic trough solar plants.

The classical parabolic trough solar plant annual simulation approach typically relies on simplified stationary collector models that are built from empiric efficiency data. This type of approach, however, has a major drawback in the fact that it does not model many important physical phenomena that occur in the collector, such as the dynamic effects, e.g. time constant and transport delay, fluid velocity and wind speed influence on efficiency. Furthermore, it does not contemplate specific solar field geometry in detail, such as the row and series bidimensional distribution, typically considering the entire solar
