7 **Abstract** Rock salt is one of the major materials used for nuclear waste geological disposal. The
8 desired characteristics of rock salt, i.e., high thermal conductivity, low permeability, and self-healing
9 are highly related to its crystalline microstructure. Conventionally, this microstructural effect is
10 often incorporated phenomenologically in macroscopic damage models. Nevertheless, the thermo-
11 mechanical behavior of a crystalline material is dictated by the nature of crystal lattice and microme-
12 chanics (i.e., the slip-system). This paper presents a model proposed to examine these fundamental
13 mechanisms at the grain scale level. We employ a crystal plasticity framework in which single-crystal
14 halite is modeled as a face-centered cubic (FCC) structure with the secondary atoms in its octahedral
15 holes, where a pair of Na^+ and Cl^- ions forms the bond basis. Utilizing the crystal plasticity frame-
16 work, we capture the existence of an elastic region in the stress space and the sequence of slip sys-
17 tem activation of single-crystal halite under different temperature ranges. To capture the anisotropic
18 nature of the intragranular fracture, we couple a crystal plasticity model with a multi-phase-field for-
19 mulation that does not require high-order terms for the phase field. Numerical examples demonstrate
20 that the proposed model is able to capture the anisotropy of inelastic and damage behavior under
21 various loading rates and temperature conditions.

23 **1 Introduction**

24 The demands for safe and permanent disposal of nuclear waste in geologic formations date back
25 over decades. Natural rock salt, found in domal and bedded formations and the re-consolidated coun-
26 terpart formed in a high-pressure and high-temperature environment, has been used for geological
27 repositories of nuclear waste disposal in the United States and Germany [1]. Two operating facilities
28 include the Waste Isolation Pilot Plant (WIPP) in Carlsbad (New Mexico, USA), and the Endlager
29 für radioaktive Abfälle Morsleben (ERAM) site in Morsleben, Germany [2].

30 The decision to use salt formation for storage and disposal of radioactive wastes is attributed to
31 its desirable thermo-hydro-mechanical-chemical characteristics, i.e., (1) high thermal conductivity,
32 (2) low permeability, (3) self-healing mechanism and, (4) biologically inactivity of rock salt (as com-
33 pared with clay). Firstly, the heat generated from nuclear wastes can be dissipated to the surrounding
34 area much faster in salt than in other materials since the host salt rock exhibits high thermal con-
35 ductivity [3]. In addition, the permeability of rock salt is sufficiently low that it is often idealized as
36 impermeable. Therefore, it may function as a secured barrier for radioactive wastes [4]. Finally, the
37 creeping property of salt enables microcracks or damage under mechanical load to be self-sealed,
38 which may also naturally guarantee the necessary geological barrier function (e.g., von Berlepsch
39 and Haverkamp [2], Chan et al. [5]).
