ABSTRACT

Evaluation of survival models to predict cancer patient prognosis is one of the most important areas of 27 emphasis in cancer research. A binary classification approach has difficulty directly predicting survival 28 due to the characteristics of censored observations and the fact that the predictive power depends on 29 the threshold used to set two classes. In contrast, the traditional Cox regression approach has some draw- 30 backs in the sense that it does not allow for the identification of interactions between genomic features, 31 which could have key roles associated with cancer prognosis. In addition, data integration is regarded as 32 one of the important issues in improving the predictive power of survival models since cancer could be 33 caused by multiple alterations through meta-dimensional genomic data including genome, epigenome, 34 transcriptome, and proteome. Here we have proposed a new integrative framework designed to perform 35 these three functions simultaneously: (1) predicting censored survival data; (2) integrating 36 meta-dimensional omics data; (3) identifying interactions within/between meta-dimensional genomic 37 features associated with survival. In order to predict censored survival time, martingale residuals were 38 calculated as a new continuous outcome and a new fitness function used by the grammatical evolution 39 neural network (GENN) based on mean absolute difference of martingale residuals was implemented. To 40 test the utility of the proposed framework, a simulation study was conducted, followed by an analysis of 41 meta-dimensional omics data including copy number, gene expression, DNA methylation, and protein 42 expression data in breast cancer retrieved from The Cancer Genome Atlas (TCGA). On the basis of the 43 results from breast cancer dataset, we were able to identify interactions not only within a single dimen- 44 sion of genomic data but also between meta-dimensional omics data that are associated with survival. 45 Notably, the predictive power of our best meta-dimensional model was 73% which outperformed all of 46
the other models conducted based on a single dimension of genomic data. Breast cancer is an extremely the other models conducted based on a single dimension of genomic data. Breast cancer is an extremely heterogeneous disease and the high levels of genomic diversity within/between breast tumors could 48 affect the risk of therapeutic responses and disease progression. Thus, identifying interactions within/be- 49 tween meta-dimensional omics data associated with survival in breast cancer is expected to deliver 50 direction for improved meta-dimensional prognostic biomarkers and therapeutic targets. 51

56 1. Introduction

 Translational bioinformatics is one of the most prominent fields that efficiently translate genomic and biomedical data into clinical knowledge for application [\[3,4,41\]](#page--1-0). In particular, translational bioinformatics has been playing important roles in cancer research 61 due to the tumor heterogeneity $[4]$. For example, recent standard-of-care for breast cancer or non-small cell lung cancer includes quantitating panels of gene expression such as Oncotype DX, developed by Genomic Health, or sequencing of genes such

<http://dx.doi.org/10.1016/j.jbi.2015.05.019> 1532-0464/© 2015 Published by Elsevier Inc. as EGFR, respectively, in order to provide therapeutic knowledge 65 for new subtypes of cancer patients $[4]$. One of the most exciting 66 problems in translational bioinformatics is to predict clinical out-

67 comes using molecular datasets such as somatic mutation, copy 68 number or gene expression data for better diagnostics, prognostics, 69 and further therapeutics $[3]$. Among problems of predicting clinical \qquad 70 outcomes, there is an increasing difficulty in predicting prognosis 71 and therapeutic response prediction $[31]$. $[32]$

Evaluating survival models is one of the most important atten- 73 tions in the development of cancer prognostic models, especially 74 based on genomic profiles. One of the common approaches is that 75 patients can be divided into two groups, such as high-risk survival 76 and low-risk survival group, according to a survival-time 77

 threshold, and then a binary classification algorithm can be applied to predict the survival group for each individual patient in a test dataset [\[24,26,27,52,57\]](#page--1-0). This approach has an advantage of pro- viding natural performance metrics from two by two contingency tables, along with positive and negative predictive values, to enable unambiguous assessments for survival prediction. However, this approach has a few limitations for predicting sur- vival in cancer. First, it is not easy to take the censored survival information into consideration when building a model. In addition, the performance of binary classification depends on the threshold selected based on patient's survival information, which was used 89 to define the two survival groups $[14]$. Alternatively, many studies have been using Cox proportional hazards models for cancer prog- nosis [\[10\]](#page--1-0). However, the final model from Cox regression approaches is an additive model. Thus, it is difficult to capture non-linear interactions between genomic features, which might 94 have important roles associated with survival $[16]$. Even though many studies have shown an association between gene expression data and patient survival using Cox regression approaches [\[2,15,53\]](#page--1-0), gene expression as a single dimensional genomic data type may not be enough to fully predict survival because cancer could be caused by multiple alterations through meta-dimensional genomic data including genome, epigenome, 101 transcriptome, and proteome [\[17\].](#page--1-0)

 Many clinical data and meta-dimensional omics data have been generated from large-scale initiatives such as the International 104 Cancer Genome Consortium (ICGC) or The Cancer Genome Atlas (TCGA). The explosion of these unprecedented dataset has pro- vided many opportunities to examine the complex genetic archi- tecture of several cancers and improve the diagnosis, treatment, and ultimately prevention of cancer [\[21,35,45–47\].](#page--1-0) Despite these efforts, it is crucial to develop a novel data integration method to better predict cancer clinical outcome, further exploring a global view on the interactions within/between meta-dimensional geno-mic data [\[23,24,27,28,39,44,56\]](#page--1-0).

 Previously, we proposed many methodological frameworks that predict clinical outcomes by integrating multi-omics data [\[23,24,27,28\]](#page--1-0). However, these binary classification approaches have difficulties to directly predict survival data due to the problems of 117 setting threshold and the characteristics of censored observations. In the present study, we propose a novel framework designed to perform three functions simultaneously: (1) predicting censored survival data; (2) integrating meta-dimensional omics data; (3) identifying interactions within/between meta-dimensional geno- mic features associated with survival outcome. In order to demon- strate the utility of the proposed framework, we applied the framework on a simulation dataset followed by the breast cancer data from TCGA. Breast cancer is an extremely heterogeneous dis-126 ease [\[22\]](#page--1-0). High degree of diversity within/between breast tumors could affect the risk of therapeutic responses and disease progres-128 sion [\[36\].](#page--1-0) In addition, most breast cancer studies based on molecu- lar data have mainly focused on one- or two-dimensions of genomic data, mostly copy number alteration or gene expression profiles [\[12,42,43\].](#page--1-0) Thus, identifying interactions within/between meta-dimensional omics data associated with survival outcome in breast cancer is expected to deliver direction for improved meta-dimensional prognostic biomarkers and therapeutic targets.

135 2. Materials and methods

136 2.1. Data

 Normalized and preprocessed multi-omics datasets in breast cancer were downloaded from TCGA data matrix [\(http://tcga-](http://tcga-data.nci.nih.gov/tcga/) [data.nci.nih.gov/tcga/\)](http://tcga-data.nci.nih.gov/tcga/) and cBio Cancer Genomics Portal [\(http://](http://www.cbioportal.org/public-portal/) www.cbioportal.org/public-portal/) (Table 1). Four different

Table 1

TCGA breast cancer data types used for meta-dimensional analysis.

genomic data types were used for this study to represent each 141 dimension of genomic data; CNA as genome dimension, methyla- 142 tion as epigenome dimension, gene expression as transcriptome 143 dimension, and protein data as proteome dimension. Each genomic 144 dataset was retrieved as a gene-based feature in order to better 145 interpret the results. CNA data was obtained from the cBio Portal 146 in order to retrieve the significantly altered copy number regions 147 across a set of cancer patients using the GISTIC method [\[7\]](#page--1-0). For 148 CNA data, 473 genes with log2 copy number value were extracted 149 from 62 significant altered regions. DNA methylation data was also 150 retrieved as a gene-level feature from the TCGA data matrix by 151 choosing the least correlated with gene expression when genes 152 were mapped with multiple methylation probes, from 485,577 153 methylation probes to 19,943 genes. The beta-value of human 154 methylation 450 BeadChip was used for the elements of methyla- 155 tion data. Gene expression data from RNA-seq consisted of 20,502 156 unique gene symbols with upper quartile normalized RSEM count 157 estimates [\[30\]](#page--1-0). Protein or phosphoprotein levels measured by the 158 reverse phase protein array (RPPA) were retrieved from the cBio 159 Portal [\[50\]](#page--1-0). Protein data contains 131 proteins after removing 11 160 proteins due to the missing data. Patients that have overlap among 161 four types of omics data with available survival and age informa- 162 tion, 476 patients, were used for this study. 163

2.2. Analysis Tool for Heritable and Environmental Network 164 Associations (ATHENA) 165

ATHENA was developed to uncover the meta-dimensional mod- 166 els that examine the genetic etiology of complex diseases such as 167 cancer. Thus, ATHENA provides three key functions: (1) performing 168 feature selection from categorical or continuous independent vari- 169 ables; (2) modeling single variable and/or interaction effects to 170 predict categorical or continuous clinical outcomes; (3) annotating 171 the candidate models for the interpretation in translational bioin- 172 formatics [\[19,24,51\].](#page--1-0) ATHENA contains several subcomponents: 173 preprocessing, modeling, and an evolutionary-algorithm based 174 machine learning technique at its core [\(Fig. 1\)](#page--1-0). The current imple-
175 mentation of ATHENA contains two different 176 evolutionary-algorithm modeling methods, which are 177 Grammatical Evolution Neural Networks (GENN) and 178 Grammatical Evolution Symbolic Regression (GESR). We have 179 extended ATHENA to perform integrative analysis using 180 meta-dimensional omics data to identify models that underlie 181 the multi-layered architecture of cancer. A schematic overview of 182 the ATHENA was shown in [Fig. 1](#page--1-0). ATHENA can simultaneously ana-
183 lyze meta-dimensional genomic data such as CNA, methylation, 184 gene expression, and protein expression data to build the 185 meta-dimensional models of complex disease. For the further anal- 186 ysis, we used GENN as the modeling component. 187

2.3. Grammatical Evolution Neural Networks (GENN) 188

Even though many computational methods such as multifactor 189 dimensionality reduction (MDR) have been proposed to discover 190 interactions between genomic features $[9,38]$, many of them 191
