ABSTRACT

Mixed convection heat transfer in a two-dimensional trapezoidal lid-driven enclosure filled with nanofluids 17 heated from below is numerically studied. The governing equations for both fluid flow and heat transfer are 18 solved by using the finite volume method (FVM). The bottom wall of the enclosure is heated while the upper 19 wall is cooled at lower temperature and the other two sidewalls are adiabatic. Four types of nanofluids (Al₂O₃, 20 CuO, SiO₂, and TiO₂ with pure water) with nanoparticle volume fraction (ϕ) in the range of 1–4% and nanoparticle 21 diameter in the range 25-70 nm were used. This investigation covers Richardson number and Reynolds number 22 in the ranges of 0.1–10 and 100–1200, respectively. The trapezoidal lid-driven enclosure was studied for different 23 rotational angles (Φ) in the range of 30°–60°, different inclination sidewalls angles (γ) in the range of 30°–60° 24 and various aspect ratios (A) ranged from 0.5 to 2. This investigation is also examined the opposing and aiding 25 flow conditions. The results show that all types of nanofluids have higher Nusselt number compared with pure 26 water. It is found that SiO₂-water has the highest Nusselt number followed by Al₂O₃-water, TiO₂-water, and 27 CuO-water. The Nusselt number increases as the volume fraction increases but it decreases as the diameter of 28 the nanoparticles of nanofluids increases. The Nusselt number increases with the decrease of rotational angle 29 and inclination angle from 30° to 60° and with the increase of aspect ratio. The results of flow direction show 30 that the aiding flow gives higher Nusselt number than the opposing flow. 31

43 1. Introduction

Mixed convection heat transfer in a lid-driven enclosure had been a 44 subject of interest in many research studies. Mixed convection flow in 45 lid-driven cavities or enclosures occurs as a result of two competing 46 mechanisms. The first one is due to shear flow which caused by the 47movement of one of the walls of the cavity while the second one is due 4849 to buoyancy flow produced by non-homogeneity of the cavity thermal boundaries. Understanding these mechanisms is of a great significance 50from technical and engineering standpoints. There were many geometric 5152shapes of the lid-driven enclosures that had been studied in the past decades considering various combinations of the imposed temperature gra-53 dients and cavity configurations. The common geometric shapes are 5455circle, square, rectangular and triangular. However, little studies on a two-dimensional trapezoidal lid-driven enclosure have been carried out 56

These types of lid-driven 57 enclosures are used in many engineering applications such as food pro- 58 cessing, lubrication technologies, thermal-hydraulics of nuclear reactors, 59 electronic cooling, crystal growth, flow and heat transfer in solar ponds, 60 dynamics of lakes, and float glass production [1]. 61

The mixed convection heat transfer in trapezoidal lid-driven enclo- 62 sures occurred in many industrial devices using conventional fluids 63 such as water, propylene glycol or ethylene glycol. However, the low 64 thermal conductivity has always been the primary limitation in the 65 development of energy-efficient heat transfer fluids, performance and 66 compactness of many engineering equipment such as electronic devices 67 and heat exchanger. In order to overcome this limitation, there is a strong 68 motivation to improve advanced heat transfer fluids with substantially 69 higher thermal conductivity. Hence, in recent years, nanofluids have 70 attracted more attention for cooling in various industrial applications. 71 This new generation of heat transfer fluids consists of suspended nano-72 particles, which have a better suspension stability compared to millime-73 ter or micrometer size ones. Various types of powders such as polymeric 74 particles, non-metallic, and metallic can be added into base fluids 75 to form slurries. Thus, the heat transfer characteristics will be enhanced 76 by using class of fluids called nanofluids. The convective heat transfer 77

characteristics of nanofluids depend on the thermophysical properties of
the base fluid and the ultrafine particles, the flow structure, the volume
fraction of suspended particles, the dimensions and the shape of these
particles. Because the prospect of nanofluid is very promising, many
studies on convective heat transfer using nanofluid have been reported
in the recent years [2–5].

Understanding the phenomena of the recirculating flow within the cavity is treated as one of the fundamental studies to fluid-dynamics researchers and hence has been pursued extensively. Abu-Nada and Chamkha [1] studied numerically steady laminar mixed convection flow in a lid-driven inclined square enclosure filled with Al₂O₃-water nanofluid. It was concluded that the heat transfer mechanisms and the 89 flow characteristics inside the cavity were strongly dependent on the 90 Richardson number. The mixed convection heat transfer in a two- 91 dimensional enclosure trapezoidal cavity filled with air was studied nu- 92 merically by Mamun, et al. [6]. It was observed that the average Nusselt 93 number increases with increasing the aspect ratio for all rotational angles. 94 The average Nusselt number was also sensitive to rotational angle. Yang 95 [7] studied numerically laminar mixed convection of air in a shear-and 96 buoyancy-driven cavity having a locally heated lower wall and moving 97 cooled sidewalls. It was observed that the flow and temperature fields 98 were symmetrical about the midlength of the enclosure because of the 99 symmetry of the boundary conditions in the vertical direction.

The mixed convection heat transfer characteristics in a lid-driven 101 2-D square cavity with various Richardson and Prandtl numbers were 102 studied by Cheng [8]. It was concluded that the heat transfer increases 103 continuously with increasing both Re and Gr numbers for Ri = 0.01 but 104 it was not for $0.5 \le \text{Ri} \le 100$. Basak, et al. [9] studied numerically mixed 105 convection flows in a lid-driven square cavity filled with porous medium 106 by using penalty finite element analysis. It was concluded that the 107 average Nusselt numbers were almost invariant with Gr number for 108 Pr = 0.7 with all Da number for linearly heated side walls or cooled 109 right wall. Basak, et al. [10] performed a numerical analysis to study the 110 influence of linearly heated side walls or cooled right wall on mixed con-111 vection lid-driven flows in a square cavity. It was shown that (Nu_b) was 112 equal to zero on the left edge of the bottom wall but it increases towards 113 the right edge of the bottom wall in the cooled right wall case.

Basak, et al. [11] investigated the influence of uniform and non- 115 uniform heating of bottom wall on mixed convection lid-driven flows 116 in a square cavity using finite element method. It was concluded that 117 the heat transfer rate for uniform heating was always more as compared 118 to the non-uniform heating. Pingan, et al. [12] employed numerical 119 method to investigate 2D laminar natural convection in a square cavity 120 containing a circular pipe. It was concluded that the original distribution 121 of temperature in square cavity was influenced by the quantity of heat 122 transfer through the pipe surface. Kandaswamy, et al. [13] studied nu-123 merically the buoyancy driven convection in a square cavity induced 124 by two mutually orthogonal and arbitrarily located baffles. It was con-125 cluded that the net heat transfer in the cavity can be enhanced by in-126 creasing the vertical baffle length regardless of its position. 127

Cianfrini, et al. [14] studied numerically natural convection in air- 128 filled, tilted square enclosures. It was concluded that for a sufficiently 129 wide range of γ around 135° the overall amount of heat transferred 130 along the x-direction across the cavity is larger than that corresponding 131 to the untilted case. Al-Amiri, et al. [15] studied numerically steady 132 mixed convection in a square lid-driven cavity under the combined 133 buoyancy effects of thermal and mass diffusion. It was found that Lewis 134 number has an insignificant effect on the isotherms and streamlines for 135 small Richardson numbers. Ho, et al. [16] studied numerically the effects 136 due to uncertainties in effective dynamic viscosity and thermal conduc-137 tivity of the Al₂O₃-water nanofluid on laminar natural convection heat 138 transfer in a square enclosure. It was observed that the uncertainties associated with different formulas adopted for the effective thermal con-140 ductivity and dynamic viscosity of the nanofluid have a strong bearing 141 on the natural convection heat transfer characteristics in the enclosure. 142

Basak, et al. [17] studied numerically the steady laminar natural con- 143 vection flow in a square cavity with uniformly and non-uniformly heat- 144 ed bottom wall using finite element method. The local Nusselt number 145 at the bottom wall was least at the center for uniform heating and there 146 were two minimum heat transfer zones at the center and the corner 147 points for non-uniform heating. Moallemi and Jang [18] investigated 148 numerically the flow and heat transfer in a lid driven square cavity. It 149 was found that the influence of buoyancy force on the flow and heat 150 transfer in the cavity is more pronounced for higher values of Pr num- 151 ber, if Re and Gr numbers are kept constant. Reima, et al. [19] studied 152 numerically the flow of a viscous thermally-stratified fluid in a square 153 container. It was observed that when the frequency parameter (ω') is 154
