#### ABSTRACT

Performing sequences of movements is a ubiquitous skill that involves dopamine transmission. However, it is unclear which components of the dopamine system contribute to which aspects of motor sequence learning. Here we used a genetic approach to investigate the relationship between different components of the dopamine system and specific aspects of sequence learning in humans. In particular, we investigated variations in genes that code for the catechol-O-methyltransferase (COMT) enzyme, the dopamine transporter (DAT) and dopamine D1 and D2 receptors (DRD1 and DRD2). COMT and the DAT regulate dopamine availability in the prefrontal cortex and the striatum, respectively, two key regions recruited during learning, whereas dopamine D1 and D2 receptors are thought to be involved in long-term potentiation and depression, respectively. We show that polymorphisms in the COMT, DRD1 and DRD2 genes differentially affect behavioral performance on a sequence learning task in 161 Caucasian participants. The DRD1 polymorphism predicted the ability to learn new sequences, the DRD2 polymorphism predicted the ability to perform a previously learnt sequence after performing interfering random movements, whereas the COMT polymorphism predicted the ability to switch flexibly between two sequences. We used computer simulations to explore potential mechanisms underlying these effects, which revealed that the DRD1 and DRD2 effects are possibly related to neuroplasticity. Our prediction-error algorithm estimated faster rates of connection strengthening in genotype groups with presumably higher D1 receptor densities, and faster rates of connection weakening in genotype groups with presumably higher D2 receptor densities. Consistent with current dopamine theories, these simulations suggest that D1-mediated neuroplasticity contributes to learning to select appropriate actions, whereas D2-mediated neuroplasticity is involved in learning to inhibit incorrect action plans. However, the learning algorithm did not account for the COMT effect, suggesting that prefrontal dopamine availability might affect sequence switching via other, non-learning, mechanisms. These findings provide insight into the function of the dopamine system, which is relevant to the development of treatments for disorders such as Parkinson's disease. Our results suggest that treatments targeting dopamine D1 receptors may improve learning of novel sequences, whereas those targeting dopamine D2 receptors may improve the ability to initiate previously learned sequences of movements.

#### 56 1. Introduction

Learning sequences of movements involves the dopamine system (Badgaiyan, Fischman, & Alpert, 2007, 2008; Karabanov et al., 2010), yet it is unclear whether different components of the dopamine system affect different aspects of sequence learning. The current study investigated this issue by studying whether geneticallydetermined individual differences in dopamine-related neuronal physiology affect various aspects of sequence learning. In particu-

http://dx.doi.org/10.1016/j.nlm.2015.09.009 1074-7427/© 2015 Published by Elsevier Inc. lar, we were interested in the function of dopamine D1 and D2 receptors, which may play different roles in learning (Kravitz & Kreitzer, 2012; Schultz, 2013). As both the prefrontal cortex and the striatum are involved in learning (e.g., Nakamura et al., 2001; Sakai et al., 1998), we were also interested in the role of the catechol-O-methyltransferase enzyme (COMT) and the dopamine transporter (DAT), which regulate dopamine catabolism in the pre-frontal cortex and dopamine reuptake in the striatum, respectively.

Several studies have reported a relationship between sequence72learning and polymorphisms in genes that code for COMT, DAT73and the dopamine D2 receptor (Noohi et al., 2014; Schuck et al.,742013; Simon et al., 2011; but see Witte et al., 2012). These studies75used tasks in which sequence learning is inferred from reaction76

77 time difference scores (e.g., Nissen & Bullemer, 1987). However, 78 there is emerging evidence that these measures are prone to floor 79 effects (Kaufman et al., 2010; Urry, Burns, & Baetu, 2015) and are, 80 therefore, unreliable when investigating individual differences. 81 Here, we used a novel sequence learning task, in which learning 82 is inferred from predictive accuracy rather than reaction time. 83 Importantly, our task was designed to measure three distinct aspects of sequence learning, namely, the ability to learn new 84 85 sequences of movements, the ability to switch flexibly between 86 two learnt sequences, and the ability to perform a previously learnt 87 sequence following interference, caused by performing the individ-88 ual movements in random order. It is possible that these three 89 aspects engage different neurological mechanisms, in which case variations in dopaminergic genes might differentially affect these 90 91 three measures.

#### 92 1.1. Dopamine D1 and D2 receptors

93 Past research suggests that dopamine D1 and D2 receptors may be involved in learning to select versus learning to inhibit actions, 94 95 respectively (Kravitz & Kreitzer, 2012; Schultz, 2013). Such learning 96 may occur as a result of experiencing a prediction error, i.e., a dis-97 crepancy between the brain's predicted outcome and the observed 98 outcome. According to this hypothesis, positive prediction errors 99 caused by unexpected outcomes generate striatal phasic dopamine 100 release that is sufficient to activate low-affinity D1 receptors. As 101 these receptors are thought to be involved in synaptic plasticity 102 along the striatonigral 'direct' pathway (Shen, Flajolet, Greengard, & Surmeier, 2008), they may play a direct role in learning to select 103 104 appropriate actions: D1-mediated long-term potentiation of 105 synapses along the striatonigral pathway would facilitate the execution of motor plans that have been followed by correct feedback. 106 107 In contrast, as dopamine D2 receptors might be involved in longterm depression in striatopallidal 'indirect pathway' neurons 108 109 (Shen et al., 2008), it is possible that they play a critical role in learn-110 ing to inhibit prepared or ongoing action plans. It is hypothesized 111 that dips in dopamine phasic firing in response to negative predic-112 tion errors caused by the omission of an expected outcome (Schultz. 113 Dayan, & Montague, 1997; Tobler, Dickinson, & Schultz, 2003) 114 result in striatopallidal neurons being released from the tonic inhi-115 bition exerted by D2 receptors. This plasticity mediated by D2 receptors is thought to strengthen the indirect pathway, which 116 could prevent the execution of incorrect motor plans (Frank, 2005). 117 118 Consequently, we hypothesized that a polymorphism in the

DRD1 gene (rs686) that has been shown to influence receptor den-119 120 sity affects the ability to learn by trial-and-error the correct stim-121 ulus-response mappings in a sequence learning task. In contrast, 122 we expected a polymorphism in the DRD2 gene (rs1800497) to 123 affect the ability to unlearn, or suppress, the tendency to perform 124 incorrect stimulus-response mappings. As behavioral performance 125 might reflect both processes simultaneously (i.e., a performance improvement might reflect both learning to select correct actions 126 and learning to inhibit incorrect ones), we used computational 127 128 modelling to separately estimate the speed with which each par-129 ticipant learned to select versus inhibit motor plans. We simulated 130 participant performance using an associative model that learns via 131 a prediction-error algorithm. We expected the DRD1 polymorphism to modulate the estimated speed with which connections 132 are strengthened, and the DRD2 polymorphism to modulate the 133 134 estimated speed with which connections are weakened.

#### 135 1.2. COMT

COMT is an enzyme that degrades catecholamines such as
dopamine, and is found predominantly in the prefrontal cortex.
Because it regulates dopamine availability, it is hypothesized to

play an important role in cognitive functions that seem to rely 139 on prefrontal dopamine, such as working memory (e.g., Bilder, 140 Volavka, Lachman, & Grace, 2004). The effects of a common poly-141 morphism in the COMT gene (Val<sup>158</sup>Met, rs4680) on cognitive 142 function have been extensively studied. This COMT polymorphism 143 has been linked to working memory, with some studies finding 144 increased working memory capacity in individuals with the Met/ 145 Met genotype, associated with increased prefrontal dopamine (e. 146 g., Dumontheil et al., 2011; Goldberg et al., 2003; but see Ho, 147 Wassink, O'Leary, Sheffield, & Andreasen, 2005; Tsai et al., 2003; 148 for a review see Savitz, Solms, & Ramesar, 2006). Given the possible 149 relationship between COMT and working memory, some have 150 argued that carriers of the Met allele should possess enhanced 151 learning abilities owing to a higher working memory capacity. 152 Consistent with this, Frank, Moustafa, Haughey, Curran, and 153 Hutchinson (2007) reported a reinforcement learning advantage 154 for individuals carrying the Met allele, which is especially pro-155 nounced in tasks requiring a higher working memory capacity 156 (Collins & Frank, 2012). Consequently, we expected that if the 157 Met allele would afford an advantage on any of the performance 158 aspects measured by our sequence learning task, this would be 159 mediated by a higher working memory capacity. 160

However, some studies have reported a performance advantage 161 for carriers of the Val allele, especially when the learning task 162 involves one or several reversals of the learned contingencies 163 (Krugel, Biele, Mohr, Li, & Heekaeren, 2009; Lonsdorf et al., 164 2009). A possible explanation for these results is that changes in 165 prefrontal dopamine levels might affect striatal phasic dopamine 166 release (Grace, 1991). Thus, although the Val allele is associated 167 with lower prefrontal dopamine levels, it may be associated with 168 increased phasic dopamine activity in the striatum (Bilder et al., 169 2004). Because phasic dopamine activity in the striatum seems to 170 be closely related to processing or learning from prediction errors 171 (Schultz et al., 1997), it is possible that the COMT Val allele affords 172 more flexible adaptation to changes in the environment. These 173 changes in the experienced contingencies presumably trigger large 174 prediction error signals, and heightened phasic dopamine activity 175 would allow more efficient learning from these signals, and hence 176 faster behavioral adaptation. Based on these findings, we expected 177 the Val allele to be associated with an increased ability to switch 178 flexibly between sequences in our task. Furthermore, because 179 enhanced processing of prediction error signals might be the cause 180 of this faster behavioral adaptation in Val carriers, we expected the 181 learning rates estimated by our prediction-error algorithm to be 182 larger in those carrying the Val allele. 183

#### 1.3. The dopamine transporter (DAT)

The DAT is expressed more abundantly in the striatum, where it 185 recaptures extracellular dopamine after release, thus limiting dopa-186 mine availability. A polymorphism in the DAT gene (rs28363170) 187 could affect learning by exerting an influence on striatal phasic 188 dopamine release in response to prediction errors. In favour of this 189 hypothesis, a few imaging and electrophysiology studies found a 190 relationship between this polymorphism and brain responses con-191 sistent with prediction error (Althaus et al., 2010; Biehl et al., 2011; 192 Raczka et al., 2011). Therefore, we expected this polymorphism to 193 correlate with the learning rates estimated by our prediction-194 error algorithm. 195
