This is a PDF file of an unedited manuscript that has been accepted for publication. As a service to our customers we are providing this early version of the manuscript. The manuscript will undergo copyediting, typesetting, and review of the resulting proof before it is published in its final form. Please note that during the production process errors may be discovered which could affect the content, and all legal disclaimers that apply to the journal pertain.

- The emergence of self-organised trails between two specific target areas in collective motion of social organisms is investigated by means of an agent-based model.
- An increase in the efficiency of navigation between the target areas is described.
- The shift, from the from the diffusive to the directed motion, is quantitative characterised.
- A crossover point, which corresponds to the minimal number of individuals necessary for the onset of collective motion, is identified.
- The scaling behaviour, as a function of the environment size, is clearly described by means of a finite-size scaling analysis.
