**Abstract**

Optical spectroscopic properties of Dy<sup>3+</sup> ions in Dy:CaYAIO<sub>4</sub> single crystals were investigated, aiming at evaluating the potential for visible laser applications. The crystals were grown by the Czochralski technique in reducing atmosphere in order to circumvent the color-center formation in this host material. Chemical compositions of the as-grown crystals were determined by electron probe micro-analysis. Absorption and emission spectra were recorded in the visible and near infrared spectral range at room temperature. Experimental oscillator strengths derived from the ground-state absorption transitions were used to fit the electrostatic, spin-orbit coupling as well as Judd-Ofelt intensity parameters. The theoretical electric dipole as well as magnetic dipole oscillator strengths, fluorescence branching ratios, and radiative lifetime were calculated in the framework of Judd-Ofelt theory. Experimental and calculated results showed that the yellow <sup>4</sup>F<sub>9/2</sub>→<sup>6</sup>H<sub>13/2</sub> transition features the largest branching ratio and emission cross-sections under 453-nm excitation. Fluorescence decay profiles were recorded to analyze the fluorescence lifetime of the <sup>4</sup>F<sub>9/2</sub> level. Anisotropy of magnetic-dipole transitions was observed in the spectroscopic study and discussed in detail.

**1. Introduction**

Visible lasers in the yellow spectral range are of great interests especially in the medical fields, such as the treatment of skin and eye diseases [1–4]. In spite of the great demand, techniques to achieve yellow laser emission are to date limited. Sum frequency mixing or frequency doubling of Nd<sup>3+</sup>-doped gain media provides laser emission in the yellow spectral range [5,6]. This way, however, suffers from the complexity of the system and the low efficiency which is typically a few percent. Novel frequency-doubled optically pumped semiconductor lasers (2 $\omega$ -OPSLs) are able to generate watt-level yellow laser outputs [7]. Nevertheless, they are bulky and expensive.

Trivalent dysprosium (Dy<sup>3+</sup>), which is well-known for its characteristic yellow fluorescence deriving from the <sup>4</sup>F<sub>9/2</sub>→<sup>6</sup>H<sub>13/2</sub> transition, can serve as an active ion to obtain yellow laser output. Several ground-state absorption transitions can be found in the blue spectral region which are suitable for efficient semiconductor laser pumping without requiring frequency conversion. In addition, the large energy gap (> 7000 cm<sup>-1</sup>) between the upper laser level <sup>4</sup>F<sub>9/2</sub> and the next lower energy level <sup>6</sup>F<sub>1/2</sub> indicates inefficient multi-phonon relaxation from the <sup>4</sup>F<sub>9/2</sub> level which would impede population inversion. Diode-pumped laser performances have been demonstrated on Dy<sup>3+</sup>-doped oxide and
