18 Stimuli-responsive systems

ABSTRACT

Efficient drug delivery to the posterior segment is a challenging task for the formulation scientist. Current treat-19 ment of chronic back-of-the-eye conditions requires frequent intravitreal injections of drug containing solutions 20 due to the short half-life and limited tissue permeation of the administered molecules. Sustained release ocular 21 delivery systems offering reduced administration frequencies have therefore gained popularity over recent years 22 with a few implants already on the market and many more in the pipeline. However, current implants generally 23 release drug at a predetermined rate without the ability to alter release rates. As required drug concentrations 24 may change over the course of treatment due to the individual patient's clinical response, implants from 25 which release rates can be tuned could optimize treatment efficacy. This article provides an overview of diseases 26 of the posterior segment of the eye, describes currently available implants to treat such conditions and discusses 27 advantages and disadvantages of various implant locations. Finally, stimuli-responsive drug delivery technolo-28 gies that have been investigated for, or have the potential to be applied to, drug delivery to the back of the eye will be discussed. Emphasis is hereby placed on polymeric implants responsive to an electric current, light or a magnetic field to achieve tunable drug release. 31

62 1. Introduction

63 With the advances in polymer science and nanomaterial development for biomedical applications over recent years there has been a 64 paradigm shift from conventional to stimuli-responsive or tunable de-65 vices [1–6], with such systems also having great potential in the area 66 of ocular drug delivery [7–9]. Effective and sustained drug delivery to 67 68 the posterior segment of the eye is challenging as there are structural 69 and physiological barriers which limit the penetration of topically or systemically administered actives into the ocular tissues. Thus, to treat 70 ocular conditions of the posterior segment of the eye, invasive local 71 therapy such as intravitreal injection of drug containing solutions is 7273 generally required. Since these injections have to be performed relative-74ly frequently by a specialist they increase the burden on health care pro-75fessionals. Moreover, they only provide modest relief and generally 76result in low patient adherence to the therapy [10]. Finally, they may re-77 sult in unwanted ocular complication such as cataract formation or ret-78 inal detachment [11].

Ocular implants provide a platform for sustained release of drugs 79 from either biodegradable or non-biodegradable polymeric systems 80 over several months to years [12]. Currently, there are three ocular im-81 plants, Vitrasert®, Retisert® and Ozurdex®, approved by the FDA, with 82 83 the first two being non-biodegradable systems anchored to the sclera while the latter is a biodegradable rod injected into the vitreous. Anoth-84 er non-biodegradable implant, Iluvien®, is currently awaiting FDA ap-85 proval, but has already been approved in some EU countries [13-18]. 86 87 However, while these systems can deliver the drug over long periods of time, the release rate cannot be altered. Thus, stimuli-responsive 88 89 drug delivery systems (DDS) suitable for ocular implantation are of in-90 terest as they have the potential to provide tunable drug delivery to the affected areas [19,20]. Such systems offer fine control over drug re-91 92lease, helping to optimize therapeutic outcomes in individual patients [21] and could become particularly attractive for delivery of macromol-93 ecules in the treatment of ocular diseases [22]. 94

95Stimuli-responsive systems are considered 'intelligent' as they re-96 spond to a stimulus leading to the initiation, termination, increase or de-97 crease in drug release. Such implants are generally divided into closed-98 loop and open-loop systems. Closed-loop systems are self-regulating 99 where an internal stimulus, such as a rise in glucose concentration in 100 the blood, increases drug release [23]. Open-loop systems require an external stimulus, such as application of an electrical current or a magnetic 101 102field, to achieve the desired response [24]. To date, only open-loop systems have been explored for the purpose of drug delivery to the poste-103rior segment of the eye, although pressure responsive closed-loop 104 systems may have great potential in the treatment of glaucoma. This 105article discusses the current treatment options for the most prominent 106 chronic posterior segment conditions highlighting the need for stimuli-107 responsive drug delivery. It then provides an overview of various implant 108 locations suggesting possible sites for stimuli-responsive tunable im-109 plantable systems. Finally, various types of implants are reviewed with 110 111 a focus on systems responsive to an electric current, light or a magnetic field and their practical application for tunable drug delivery to the 112 posterior segment of the eye. 113

114 **2.** Current pharmacological therapies for posterior eye conditions

Posterior segment diseases are a major health concern as these conditions directly impact on the patient's vision and therefore their quality of life. Around 285 million people are estimated to be visually impaired or blind with this number increasing by at least seven million per year 118 [25]. The main vision threatening diseases affecting the posterior seg- 119 ment include age-related macular degeneration (AMD), diabetic reti- 120 nopathy and uveitis. While a number of drugs are available to treat 121 these conditions, only a few implantable devices exist to delivery 122 these drugs efficiently and over extended periods of time. Table 1 123 gives an overview of implantable DDS approved by the FDA or in the 124 pipeline for the treatment of posterior eye conditions with individual 125 diseases described below and novel implantable systems further 126 discussed in a later section.

128

159

2.1. Cytomegalovirus (CMV) retinitis

CMV is an opportunistic virus which can infect ocular tissues includ- 129 ing the retina and is most prominent in patients with acquired immune 130 deficiency syndrome (AIDS), affecting up to 25% of these patients [13, 131 40-42]. Without treatment CMV can lead to vision loss and is the lead- 132 ing cause of blindness in patients with compromised immunity [43]. 133 Ganciclovir is the most studied drug for the treatment of this disease 134 and is considered the first line of treatment [44]. Initially ganciclovir 135 was given to CMV retinitis patients intravenously; however, this was as- 136 sociated with systemic side effects including neutropenia [45]. Later the 137 intravitreal route was used to deliver the drug directly into the eye, 138 which resulted in reduced systemic exposure. However, intravitreal in- 139 jections are associated with low patient compliance and may cause cat- 140 aract formation and retinal detachment [46]. These factors encouraged 141 the development of an intravitreal ganciclovir implant (Vitrasert) 142 which has shown good therapeutic outcomes in AIDS patients suffering 143 from this eye condition, although raised intraocular pressure (IOP) and 144 cataract formation have arisen as complications. Vitrasert releases 5 mg 145 of drug at a predetermined rate over several months, achieving intravit- 146 real drug levels of 4 µg/ml [15,46-48]. As some patients with compro- 147 mised immunity (especially solid organ transplant patients [47]) have 148 developed ganciclovir resistant CMV retinitis infection, another anti- 149 viral drug, foscarnet, either alone or in combination with ganciclovir, 150 has been administered intravitreally to cure this infection. Therefore, 151 an implant containing both drugs with the possibility to modify the re- 152 lease in response to a stimulus could offer an advantage over Vitrasert 153 [49,50]. Cidofovir is another antiviral drug used for the treatment of 154 CMV retinitis. It has a narrow intravitreal therapeutic index [51], thus 155 a carefully designed controlled release implant would ensure therapeu- 156 tic concentrations are maintained. Nevertheless, emerging resistance 157 and treatment failures may limit this opportunity [52]. 158

2.2. Age-related macular degeneration (AMD)

AMD is the leading cause of irreversible blindness in the population 160 aged over 50 years with its prevalence projected to increase up to 50% 161 in this age group by 2020 [53–55]. Early stage AMD is characterized by 162 the presence of a few medium sized drusen in the retina as well as retinal pigment abnormalities. The advanced stage of AMD can be either 164 dry (non-neovascular) or wet (neovascular). Wet AMD accounts for 165 10–15% of the overall prevalence of AMD but is responsible for over 166 80% of cases of legal blindness [56]. It is characterized by choroidal neovascularization and can lead to blindness in days to weeks as a result of 168 hemorrhage or fluid accumulation. Anti-vascular endothelial growth 169 factor (anti-VEGF) antibodies are the primary pharmacological course 170 of treatment for wet AMD administered *via* the intravitreal route. 171 These include FDA approved ranibizumab (Lucentis®) and off-label 172
