**Abstract**

Ply cracking is an inherently stochastic process due to the random variability of local material properties of the plies. Such randomness in microstructure and in failure evolution generally leads to non-uniform distributions of ply cracks. Modeling this non-uniformity is a crucial factor in predicting the initiation and propagation of matrix cracks. Therefore, a novel stress-based variational model is developed to accurately predict stress transfer and stiffness reduction in general symmetric laminates containing non-uniformly spaced ply cracks. In contrast to available approaches for uniformly spaced ply cracks based on the unit cell, the analysis is carried out for the entire laminate. Results derived from the developed method for thermo-elastic properties of the cracked laminates show an excellent agreement with finite element results. Moreover, the accuracy of predictions based on an approximate approach is discussed using a comprehensive analysis of various laminates and crack patterns for both carbon and glass fibre systems.

**1. Introduction**

Ply cracking in laminates subject to static or fatigue mechanical and thermal loading, is the initial and most typical ply-level failure phenomenon resulting from the coalescence of micro-damage. Ply cracks (also known as matrix cracks, transverse cracks, intra-laminar cracks, inclined cracks, etc.) are orthogonal to the laminate mid-plane, run parallel to fibers in the ply and usually cover the whole thickness and width of the ply in the specimen. In both standard and thin-ply composite laminates subject to fatigue loading, damage tolerance can be assured only if
