## ABSTRACT

We theoretically investigate the effects of atomic defect related short-range disorders and electron-electron interactions on Anderson type localization and the magnetic properties of hexagonal armchair graphene quantum dots using an extended mean-field Hubbard model and wave packet dynamics for the calculation of localization lengths. We observe that randomly distributed defects with concentrations between 1 and 5% of the total number of atoms leads to localization alongside magnetic puddle-like structures. Although the localization lengths are not affected by interactions, staggered magnetism and localization are found to be enhanced if the defects are distributed unevenly between the sublattices of the honeycomb lattice.

## 1. Introduction

Graphene [1–5], a promising single-layer material for electronics applications, has been getting increasing interest in understanding and engineering its properties at the nanoscale to form graphene nanoribbons and dots. Indeed, electronic, magnetic and optical properties of graphene can be tuned by changing edge, shape, doping and number of layers [6–38]. On the other hand, introducing adatoms [39–44] or vacancies [45–49] can also significantly affect its physical properties. For example, a dramatic increase in resistivity of graphene, metal-to-insulator (localization) behavior and magnetic moment induction which led to spin split state at the Fermi energy were observed in several experimental works by introducing hydrogen adatoms on graphene [41,43,50]. Additionally, local magnetism due to vacancies created by irradiation of graphene samples were detected [46,49].

There have been many theoretical attempts to explain induction of metal-to-insulator transition and magnetism brought about by adatom or vacancy related disorders in graphene structures [30,31,51–61]. For instance, ferromagnetic or antiferromagnetic behavior of quasilocalized states can be induced by introducing two atomic defects on the same or opposite sublattices of the honeycomb lattice. Furthermore, it was found that vacancy related sublattice imbalance which leads to total spin  $S \neq 0$  can induce global magnetism predicted by Lieb and sublattice balance which leads to total spin  $S = 0$  can induce local magnetism by using mean-field Hubbard model for graphene ribbons [52,62]. On the other hand, Schubert et al. [61] used a tight-binding (TB) model ignoring magnetic effects to show that low concentrations of randomly distributed hydrogen adatoms lead to metal-to-insulator

transition in graphene, although alongside formation of electron-hole puddles that tend to suppress Anderson localization [63].

An interesting and natural question to ask is whether the magnetic and localization properties are affected by each other, which, to the best of our knowledge, remains unaddressed presumably due to difficulties in incorporating electron-electron interactions in large size systems. In this work, in order to find out the role of atomic defects in both the localization of electronic states and the magnetic behavior at the nanoscale, we perform mean-field Hubbard (MFH) calculations for medium sized graphene quantum dots (GQD). More specifically, we focus on hexagonal shaped GQDs with armchair edges which are, unlike zigzag edges, free of magnetized edge effects. Thus hexagonal armchair GQDs allow for an unbiased investigation of defect induced magnetization and provide a link between nanosize and bulk limits. The localization properties are investigated using wave function dynamics. We show that localization of electronic states can occur due to atomic defects, together with formation of magnetic puddles. We found that, although the localization lengths are not affected by interactions for evenly distributed defects between the two sublattices, an uneven distribution between the two sublattices can significantly enhance both the localization and the magnetization. Surprisingly, no spin dependent localization lengths were observed.

## 2. Method and model

We use the extended one-band MFH model where the single electron states can be written as a linear combination of  $p_z$  orbitals on every carbon atom since the sigma orbitals are considered to be mainly

responsible for mechanical stability of graphene. Within the extended MFH model, Hamiltonian can be written as:

$$H_{MFH} = \sum_{ij\sigma} (t_{ij} c_{i\sigma}^\dagger c_{j\sigma} + h. c.) + U \sum_{i\sigma} \left( \langle n_{i\sigma} \rangle - \frac{1}{2} \right) n_{i\bar{\sigma}} + \sum_{ij\sigma} V_{ij} (\langle n_j \rangle - 1) n_{i\sigma} \quad (1)$$

where the first term represents the TB Hamiltonian and  $t_{ij}$  are the hopping parameters given by  $t_{nn} = -2.8$  eV for nearest neighbours and  $t_{nmm} = -0.2$  eV for next nearest-neighbours [64]. The  $c_{i\sigma}^\dagger$  and  $c_{i\sigma}$  are creation and annihilation operators for an electron at the  $i$ -th orbital with spin  $\sigma$ , respectively. Expectation value of electron densities are represented by  $\langle n_{i\sigma} \rangle$ . The second and third terms represent onsite and long range Coulomb interactions, respectively. We note however that, the inclusion of long-range Coulomb interactions did not significantly affect the numerical results in this work. This is in contrast with our previous work [26] on the investigation of long range scatterers which cause strong density modulations, leading to non-negligible long-range Coulomb interactions. We take onsite interaction parameter as  $U = 16.522/\kappa$  eV and long-range interaction parameters  $V_{ij} = 8.64/\kappa$  and  $V_{ij} = 5.33/\kappa$  for the first and second nearest neighbours with effective dielectric constant  $\kappa = 6$  [65], respectively. Distant neighbor interaction is taken to be  $1/d_{ij}\kappa$  and interaction matrix elements are obtained from numerical calculations by using Slater  $\pi_z$  orbitals [66]. To account for short-range disorder effects (which may be due to vacancies or hydrogen adatoms), we simply remove corresponding  $p_z$  orbital sites. This model assumes that sp<sup>2</sup> hybridization of atoms neighboring the defect and the honeycomb lattice are not distorted.

A critical step in the numerical calculations is the initial guess state used for the self-consistent diagonalization of the MFH Hamiltonian, as there is a high risk of getting stuck in a local energy minimum for systems with several thousands of atoms. Local version of Lieb's theorem provides a convenient way to generate the initial state. According to Lieb's theorem [62], if there is an overall imbalance between the number of A and B sublattice atoms in a bipartite lattice, a finite magnetic moment  $(N_A - N_B)/2$  arises at zero temperature. Locally, such imbalance occurs in the vicinity of atomic defects. Therefore, in our initial density matrices, we assume a surplus of spin up (down) density around type-A (B) vacancies, leading to our lowest energy solution.

Once the self-consistent Hubbard quasi-particle states  $\psi_{n\sigma}(x)$  with energy  $E_n$  are obtained, we proceed with the computation of time-dependent wave functions. Assuming an initial wave packet of the electron injected through one corner of the hexagonal QD (see Fig. 1) as  $\Psi(t=0)$  with average energy  $\langle E_i \rangle$  of width  $\delta E_i \sim t_{nn}/2$ , the evolution is

Fig. 1. Time evolution of electronic density obtained by TB model for disordered QD (containing 5514 atoms and width size 13 nm). Electron injected through one corner of the QD has average energy of  $\langle E_i \rangle = 0.38$  eV. Each column panels show the snapshot of wave packet propagation at, from left to right, time  $t = 0$ ,  $t = 30t_0$  and  $t = 10^6t_0$ . Top and bottom panels are for 2% and 5% disorder distributions, respectively.

given by  $\Psi(t) = \sum_n \langle \psi_{n\sigma} | \Psi(t=0) \rangle e^{-iE_n t/\hbar} \psi_{n\sigma}$ . When the time scale is sufficiently large,  $t \gg t_0 = \hbar/t_{nn}$ , (where  $t_0 \sim$  femto second) the system reaches a quasi-stationary state from which it is possible to deduce the localization properties [61].

### 3. Results and discussions

#### 3.1. Tight-binding results

Time evolution density plots for a  $\langle E_i \rangle = 0.38$  eV (around Fermi level) wave packet are shown in Fig. 1, at  $t = 0$ ,  $t/t_0 = 30$  and  $t/t_0 = 10^6$  (from left to right), for defects concentrations of 2% (upper panels) and 5% (lower panels). Initially, at  $t = 0$ , we assume that the injected wave packet occupies a small, defect-free region of the QD. As  $t$  is increased, the density propagates slower for higher defect concentrations, before reaching a quasi-stationary state above  $t/t_0 = 10^4$ . At higher time scales,  $t/t_0 = 10^6$  (order of nano second), the wave packet is still localized around the corner of the QD, especially visible at the higher defect concentration.

In order to investigate the localization more systematically including size dependence, in Fig. 2 we plot the injected electron's probability density as a function of distance to the lead corner, integrated over an angle of  $\pi/3$  (see Fig. 2a), and averaged over 20 randomly generated defect configurations (evenly distributed between sublattice A (50%) and B (50%) for the main frames but unevenly as A (100%) and B (0%) for the inset figure), obtained from TB calculations. Moreover, time averages over 36 samples between  $t/t_0 = 5 \times 10^5$  and  $4 \times 10^6$  were performed. Here, each column corresponds to a different size GQD having 5% defect concentration. We note that we do not show figures for concentrations less than 5%. Localization lengths denoted by  $\lambda$  were estimated for different injected electron energies (one near the Fermi level, other two in deep conduction and valence bands), by logarithmic curve fitting [61]. At 1% defect concentration, size effects dominate the densities. Estimated localization length is larger than the system size even for the largest QD (25 nm wide) and the energy dependence is weak. As the defect concentration is increased to 2%, we find  $\lambda \sim 12$  nm for 0.38 eV (Fermi level energy) for all QD sizes. At  $-1.6$  and  $2.4$  eV,  $\lambda$  exceeds the system size. Defect concentration of 5% has localization length of  $\lambda \sim 3.5$  nm for  $\langle E_i \rangle = 0.38$  eV for all QD sizes (see Fig. 2b, c and d). Additionally, we observe localization ( $\lambda \sim 6.5$  nm) for the energies  $\langle E_i \rangle = -1.6$  and  $2.4$  eV. The calculated localization lengths here are consistent with the TB results by Schubert et al. [61] obtained for ribbon geometries. Furthermore, as seen in the inset of Fig. 2b, the localization is enhanced for an unbalanced distribution of 100–0%, consistent with the finding of Ref. [67] obtained for bulk graphene.

#### 3.2. Mean-field hubbard results

In the following, we will focus on 13 nm QDs (containing 5514 atoms) in order to investigate the effects of interactions on spin densities and DOS through self-consistent mean-field Hubbard calculations.

Fig. 3 shows the spin resolved DOS for defects concentrations of 2% (upper panels) and 5% (lower panels). On the left panels, we consider equal number of randomly distributed defects on A and B sublattices (50-50%). Even though the total spin of such a system is zero as predicted by Lieb's theorem [62], a slight asymmetry can be observed between spin up and down impurity peaks in the vicinity of Fermi level, due to broken sublattice symmetry. On the other extreme, if all defects are placed on sublattice A (right panel), total spin is equal to half of the total number of defects, and a clear spin splitting is observed in DOS, a signature of ferromagnetic coupling. As expected, as the concentration of defects is increased from 2% to 5%, impurity peaks become more pronounced. The black dots represent energy values of interest which will be used below to calculate the localization lengths for wave packets with different average energies.
