## ABSTRACT

The paper undertakes a comparison of the experimental and calculated fatigue lives by using criteria formulated by Findley, Matake and Dang Van for S355J2WP, S355J2G3 and 30CrNiMo8 steels. The considered criteria include the coefficient  $k$  (the coefficient of material sensitivity to the normal or hydrostatic stresses) which originally is related to the fatigue limits. It is shown that the value of  $k$  coefficient depends on the number of cycles to failure and better results are obtained using the proposed idea of calculating the  $k$  value for number of cycles specified for analysed steels than using the original concept of the fatigue limits. Analysis of the criteria consisted in comparison of the experimental and calculated results obtained for different values of the  $k$  coefficient determined for different number of cycles. The results of calculations were compared with the experimental results for cyclic bending, torsion and proportional combination of bending with torsion.

## 1. Introduction

Fatigue of structural materials is a very complex phenomenon, and fatigue failure is dependent on various factors, such as the type and state of the material [1], geometry of the element [2,3], the kind of loading, history of loading [4–7], stress state [8,9], and residual stresses [10,11]. It is quite common [1,4,9] to use phenomenological models which reflect general macroscopic material response to fatigue loading instead of modelling of complex behaviour of material at the micro or mesoscopic scale. In such modelling the so-called reference fatigue curves which reflect general cyclic response to uniaxial fatigue loading are usually necessary for fatigue life calculation. These experimentally curves obtained, e.g. under cyclic tension–compression and torsion loadings have a form of functions between fatigue life  $N_f$  and amplitudes of applied stresses or strains [1].

In the case of the multiaxial stress state occurring usually in real structures or machine elements, it is necessary to reduce that state to an equivalent uniaxial state. Depending on the used fatigue hypothesis the equivalent state could be calculated for the whole loading history or only for amplitudes. Finally, the equivalent stress amplitude is used to calculate fatigue life via the mentioned reference curve. The present article is focused on the fatigue hypotheses

that relate the reduction of multiaxial stress state with a plane in material with fixed orientation. This methodology has gathered a lot of attention since its emerging in 1935 [13] due to its wide range of applicability and physical background [9,12,14–22]. It is known as the critical plane approach. There are numerous critical plane fatigue criteria based on various assumptions and parameters describing the fatigue processes. Some criteria are based on combination of the hydrostatic and the shear stresses [1,15,22–24], some others are linear or nonlinear functions of normal and shear stresses [15,25–27]. There are also criteria using strain energy density being a combination of energy density of normal and shear strains [1,4,15,28–30]. Participation of particular stress components occurring on the critical plane to fatigue damage in the criterion is determined by consideration of a certain number of material coefficients. The most common criteria reduce multiaxial state to equivalent shear stress state using linear relation between normal and shear stresses on the critical plane. The physical interpretation was given by Stanfield [13] as follows: the normal stress changes an internal friction forces between two surfaces in the critical plane which reduces or adds the shear fatigue endurance. Such influence of the normal stresses [1,15] depends on material type which is reflected by certain material coefficient  $k$ . This coefficient is usually derived (if possible) by application of the formula for equivalent stress to the fatigue limits obtained under uniaxial cyclic torsion, bending and push–pull loadings (reference curves). It must be noticed that using the fatigue limits restrains the application of this equivalent stress formula to regime around fatigue limit. Unless the uniaxial

## Nomenclature

|            |   |
|------------|---|
| $E$        | Young's modulus   |
| $k$        | coefficient of material sensitivity to the normal or hydrostatic stresses |
| $m_\sigma$ | fatigue strength exponent for fully reversed cyclic bending               |
| $m_\tau$   | fatigue strength exponent for fully reversed cyclic torsion               |

|                 |   |
|-----------------|---|
| $N_f$           | number of cycles to failure according to reference curve (fatigue characteristic) |
| $\sigma_{0.2}$  | yield stress  |
| $\sigma_{af,b}$ | fatigue limit for fully reversed cyclic bending                                   |
| $\sigma_{UTS}$  | ultimate tensile strength   |
| $\nu$           | Poisson ratio   |
| $\tau_{af}$     | fatigue limit for fully reversed cyclic torsion                                   |

**Table 1**

Basic mechanical properties of the considered materials.

| Material (EN) | $E$ (GPa) | $\sigma_{0.2}$ (MPa) | $\sigma_{UTS}$ (MPa) | $\nu$ (–) |
|---------------|-----------|----------------------|----------------------|-----------|
| S355J2WP      | 215       | 414                  | 556                  | 0.29      |
| S355J2G3      | 213       | 394                  | 611                  | 0.31      |
| 30CrNiMo8     | 217       | 812                  | 1014                 | 0.30      |

## 2. Experimental data

The calculated results were compared with the experimental ones for three materials: alloy steels: S355J2WP (according to PN: 10HNAP) [31] and S355J2G3 (according to PN: 18G2A) [31,32] and a medium-alloy steel 30CrNiMo8 [33]. Basic

**Fig. 1.** Specimen geometry used for fatigue tests of two steels: S355J2WP and S355J2G3 [31].

fatigue reference curves have the same fatigue strength exponents ( $m_\sigma$ ,  $m_\tau$ ). In other case, the  $k$  coefficient depends on a number of cycles to failure  $N_f$ . In spite of recent development of the critical plane approach this feature has not been noticed and studied.

The aim of the paper is to analyse the three commonly used fatigue criteria based on the critical plane concept formulated by Findley [25,26], Matak [27] and Dang Van [24] in respect to changes in  $k$  coefficient being  $m_\sigma$  different from  $m_\tau$  (the slopes of fatigue characteristics). Although, the applied criteria belongs to high cyclic fatigue regime the changes in  $k$  value cannot be disregarded. The considered criteria include the  $k$  coefficient expressed originally through the fatigue limits. The test results for bending, torsion and proportional combination of bending with torsion are used in the analysis. The analysis of the criteria consisted in comparison of experimental and calculated fatigue lives for different values of the coefficient  $k$ . Values of the coefficient  $k$  were determined for six different numbers of cycles and compared with the value obtained for the fatigue limits.
