\textbf{ABSTRACT}

\textbf{Background and purpose:} Gerstmann-Sträussler-Scheinker syndrome is a rare hereditary neurodegenerative disorder with clinical heterogeneity. This study is aimed to demonstrate the clinical spectrum and radiologic characteristics of patients caused by Pro102Leu mutation in PRNP.

\textbf{Materials and methods:} We retrospectively analyzed clinical manifestations of five patients from four Japanese families, and comprehensively analyzed their brain MRI, SPECT (N-isopropyl-p-[123I] iodoamphetamine), and PET (18F-2-fluoro-2-deoxy-D-glucose) images.

\textbf{Results:} All patients developed ataxia of lower limbs and trunk, gait disturbance, dysesthesia in legs, and lower limb hyporeflexia. In the early clinical stage before dementia began, no noticeable abnormalities could be observed from brain MRI, but SPECT and PET revealed mosaic-like patterns of blood flow and glucose metabolism in the brain. Predominant abnormalities were found in the occipital and frontal lobes on SPECT and PET analysis, respectively. In SPECT analysis, blood flow of the anterior cerebellar lobes was lower than that of the posterior cerebellar lobes.

\textbf{Conclusions:} Clinical symptoms resulting from failure of dorsal horn of spinal cord and spinocerebellar tracts were observed in all cases. Radiologic findings revealed individual differences of involved region in their brain, which could produce clinical diversity. We identified a downtrend of blood flow in the anterior cerebellar lobes, a projection field of the spinocerebellar tracts, which is an important feature of Gerstmann-Sträussler-Scheinker syndrome.

1. Introduction

Gerstmann-Sträussler-Scheinker syndrome (GSS), first reported in 1936, as a common inherited prion disease, is clinically and genetically heterogeneous \cite{1,2}. According to a recent Japanese report, GSS102 accounts for 16.3% (93/572) of patients with inherited prion disease \cite{3}. GSS102 is characterized clinically by prominent cerebellar signs accompanied by a slowly progressive dementia and pathologic findings of multifocal prion protein (PrP)-positive plaques \cite{4,5}. Spinocerebellar degeneration is known as one of the disease features and has been recognized as associated with dementia. However, dementia frequently appears later during the course of illness, which makes it difficult for neurologists to diagnose in the early stage.

Previously, we demonstrated that GSS102 mainly shows ataxia of the lower limbs and trunk, dysarthria, lower limb paresthesia, and decreased deep tendon reflexes in the early stage, followed by dementia in the advanced stage. On radiologic analysis, we have also described that SPECT imaging shows abnormalities earlier than MRI, manifesting predominantly as decreased blood flow in the occipital lobes but almost normal flow in the cerebellum \cite{6}. In this study, we further examined the higher brain function of patients with GSS102, and evaluated the image findings of MRI, SPECT, and PET.

\textbf{Abbreviations:} GSS, Gerstmann-Sträussler-Scheinker syndrome; GSS102, GSS patients caused by Pro102Leu mutation in PRNP

2. Materials and methods

We retrospectively studied five GSS patients from four families with genetically confirmed heterozygous Pro102Leu mutation in the PRNP gene. Additionally, 4 patients harbored homozygous methionine at codon 129 in PRNP, while heterozygous substitution from methionine to valine (Met129Val) was detected in patient 3. Besides, all patients shared a homozygous glutamate at codon 219. All patients were born in Kagoshima Prefecture, locating in the southern part of Japan. The protocol of the following study was reviewed and approved by the Institutional Review Board of Kagoshima University. All patients and family members provided written, informed consents to participate in this study.

2.1. Cognitive and electrophysiological studies

Neurologic examination was performed mainly in our hospital. To evaluate cognitive abnormalities, three methods were applied, consisting of the Mini Mental State Examination (MMSE), the Wechsler Adult Intelligence Scale-Revised (WAIS-R) test, and the Trail Making Test (TMT). Three of the five patients underwent electrophysiological studies, including nerve conduction study (NCS), needle electromyography (needle EMG), short latency somatosensory evoked potential (SSEP), and electroencephalogram (EEG).
