ABSTRACT

Hydrogen sulfide (H₂S) is the most recent endogenous gasotransmitter that has been reported to serve many physiological and pathological functions in different tissues. Studies over the past decade have revealed that H₂S can be synthesized through numerous pathways and its bioavailability regulated through its conversion into different biochemical forms. H₂S exerts its biological effects in various manners including redox regulation of protein and small molecular weight thiols, polysulfides, thiosulfate/sulfite, iron-sulfur cluster proteins, and anti-oxidant properties that affect multiple cellular and molecular responses. However, precise measurement of H₂S bioavailability and its associated biochemical and pathophysiological roles remains less well understood. In this review, we discuss recent understanding of H₂S chemical biology, its relationship to tissue pathophysiological responses and possible therapeutic uses.

Introduction

Hydrogen sulfide (H₂S) has emerged as an important gaseous signaling molecule playing numerous roles in health and disease, along with CO and NO [1,2]. It acts as a relaxant of smooth muscle and thus a vasodilator, a regulator of cardiac function and *N*-methyl *D*-aspartate (NMDA) receptor in the brain, and cytoprotectant and mediator for cardiovascular therapeutic approaches [3–8]. Understanding precise pathophysiological signaling mechanisms and the metabolism of H₂S is a topic of active research. And unraveling its interactions within different tissues, with other biochemical molecules and various signaling mediators is becoming ever more complex. Thus, in this rapidly growing field it is important to appreciate key findings and their potential implications regarding H₂S chemical biology that are now known, as well as to identify critical areas for further understanding and clarification. In this review, we address numerous salient issues regarding biochemical synthesis and metabolism of H₂S, measurement techniques used to detect levels of H₂S both *in vitro* and *in vivo*, biological functions regulated by H₂S and the potential of therapeutic approaches employing H₂S based therapies for various clinical applications.

H₂S biosynthesis: enzymatic and non-enzymatic

The production of H₂S can occur via two pathways – enzymatic and non-enzymatic. Enzymatic synthesis of H₂S occurs through three enzymes that are cystathionine gamma-lyase (CGL also abbreviated as CSE), cystathionine beta-synthase (CBS) and 3-mercaptopyruvate sulfurtransferase (3-MST). These enzymes have been reported to be organ-specific depending on the type of enzyme. CBS is predominantly found in the brain, nervous system, and liver [4], while CSE is mostly found in the vasculature and liver, and 3-MST can be found in the brain and vasculature [9]. However, all three enzymes are distributed across many tissues and are often jointly present such as CBS and CSE being most prominently found in the liver and kidney [9]. Importantly, while CSE and CBS are hemoproteins primarily located in the cytosol, 3-MST is a zinc-dependent protein found in both the mitochondria and cytosol.

Cystathionine is a critical intermediate metabolite involved in many sulfur-containing amino acids, formed by CBS through condensation of homocysteine along with serine. CSE is also involved in a reaction that converts L-cystathionine and cysteine to form L-cysteine and α -ketoglutarate (α -KG). CSE and CBS ultimately produce H₂S through a reaction involving the generation of L-cysteine, pyruvate, and ammonia. Likewise, 3-MST produces H₂S through a reaction involving the generation of pyruvate from 3-mercaptopyruvate (3-MP). It has recently been shown that 3-MST might also cleave mercaptopyruvate to form pyruvate and H₂S, or catalyze the transsulfuration of a thiol to a persulfide, which can subsequently join a second thiol to form a disulfide and release H₂S [10]. 3-MP substrate is provided through the metabolism of cysteine and α -KG by cysteine aminotransferase (CAT). Fig. 1 illustrates how these enzymes coordinately regulate transsulfuration

activity controlling physiological H₂S levels in a complex and overlapping manner.

Apart from enzymatic synthesis pathways, endogenous production of H₂S can also occur through other non-enzymatic processes that are less well understood. Non-enzymatic production of H₂S occurs through glucose, glutathione, inorganic and organic polysulfides (present in garlic) and elemental sulfur. H₂S can be generated from glucose either via glycolysis or from phosphogluconate via NADPH oxidase. Glucose reacts with methionine, homocysteine or cysteine to produce gaseous sulfur compounds – methanethiol and hydrogen sulfide. H₂S is also produced through direct reduction of glutathione and elemental sulfur. Reduction of elemental sulfur to H₂S is mediated through reducing equivalents of the glucose oxidation pathway such as NADH, or NADPH [11]. H₂S formation from thiosulfate results from a reductive reaction involving pyruvate, which acts as a hydrogen donor. Thiosulfate is an intermediate of sulfur metabolism from cysteine and a metabolite of H₂S that can also lead to the production of H₂S [12–14]. Though the involvement of mitochondria in oxidizing sulfide has been well known [15], the specific affinity of the enzyme 3-MST to thiosulfate and in its production has been recently reported [16,17]. Further, rhodanese is involved in metabolizing thiosulfate into H₂S and sulfite [13]. Fig. 1 summarizes various enzymatic and non-enzymatic H₂S synthesis pathways that have been described.

Different biochemical forms of sulfide

Apart from its free state, H₂S can react with different biochemical molecules establishing different bioavailable pools including stable, acid-labile and bound sulfide forms (Fig. 2). In the stable pool, sulfur atoms are not readily reactive or liberated upon chemical treatment with acid or dithiothreitol [14]. These compounds exist in a reduced divalent form such as H₂S or oxidized hexavalent form such as sulfate anion. Sulfide can also be categorized based on the form in which they are stored in a biological system such as free sulfides or in bound forms such as acid-labile forms and bound sulfane sulfur [18]. Free or unbound sulfide exists as S^{2–}, HS[–] or H₂S, where its acidic dissociation constants (pKa) range between >12 and 7.0, respectively (Fig. 2). Acid-labile sulfide is mainly in the form of iron–sulfur (Fe–S) complexes and persulfides, which play a critical role in redox reactions in cytoplasm and mitochondria. The critical pH below which H₂S is released from acid-labile sulfur like Fe–S is 5.4 [19]. Conversely, bound sulfane sulfur exists as a compound containing sulfur-bonded sulfur [20]. This includes compounds like polysulfides, thiosulfate, polythionates, thiosulfonates bisorganyl-polysulfanes or monoarylthiosulfonates and elemental sulfur. Bound-sulfane sulfur compounds such as polysulfides release H₂S under reducing conditions suggesting that cellular redox state is important for regulating its bioavailability [21]. Moreover, free H₂S can be incorporated into proteins as bound sulfane sulfur, where its divalent sulfur form binds only to the elemental sulfur, persulfides and polysulfides [22]. These various biochemical forms represent complex and diverse ways in which H₂S bioavailability can be maintained. However, the movement
