Hydrodynamic model;
Fjord circulation;
Heat and salt content
and anomalies;
Hornsund model

Summary The Arctic Ocean is currently in transition towards a new, warmer state. Understanding the regional variability of oceanographic conditions is important, since they have a direct impact on local ecosystems. This work discusses the implementation of a hydrodynamic model for Hornsund, the southernmost fjord of western Svalbard. Despite its location, Hornsund has a stronger Arctic signature than other Svalbard fjords. The model was validated against available data, and the seasonal mean circulation was obtained from numerical simulations. Two main general circulation regimes have been detected in the fjord. The winter circulation represents a typical closed fjord system, while in summer the fresh water discharge from the catchment area generates a surface layer with a net flow out of Hornsund. Also described are the local hydrographic front and its seasonal variability, as well as the heat and salt content in Hornsund. The integration of salt and heat anomalies provides additional information about the

salt flux into the innermost basin of the fjord - Brepollen during the summer. Extensive *in situ* observations have been collected in Hornsund for the last two decades but our hydrodynamic model is the first ever implemented for this area. While at the moment *in situ* observations better represent the state of this fjord's environment and the location of measurements, a numerical model, despite its flaws, can provide a more comprehensive image of the entire fjord's physical state. *In situ* observations and numerical simulations should therefore be regarded as complementary tools, with models enabling a better interpretation and understanding of experimental data.

1. Introduction

Hornsund is a fjord in the south-west of the Svalbard archipelago. Its position and wide opening to Greenland Sea shelf waters (Fig. 1), as well as the large area of contact between the coastal waters and tidewater glacier fronts, expose it to the strong influence of the shelf waters. The fjord's 12 km wide mouth faces west towards the Greenland Sea. Hornsund is 30 km long with a maximum depth of about 260 m (average

ca 90 m) (Frankowski and Ziola-Frankowska, 2014), an estimated surface area of 275 km² and a volume of 23 km³. The fjord's coastline is very diverse, with a number of small bays, which are the mouths of valleys with glaciers flowing into the sea. Some of these small bays appeared as late as the beginning of the 20th century as a result of glacier recession. The area and coastline of Hornsund have been expanding gradually since the retreat of glaciers. The total area of glacier cover in Hornsund diminished from 1899 to 2010 by
