ABSTRACT

The development of responsive biomaterials capable of demonstrating modulated function in response to dynamic physiological and mechanical changes in vivo remains an important challenge in bone tissue engineering. To achieve long-term repair and good clinical outcomes, biologically responsive approaches that focus on repair and reconstitution of tissue structure and function through drug release, receptor recognition, environmental responsiveness and tuned biodegradability are required. Traditional orthopedic materials lack biomimicry, and mismatches in tissue morphology, or chemical and mechanical properties ultimately accelerate device failure. Multiple stimuli have been proposed as principal contributors or mediators of cell activity and bone tissue formation, including physical (substrate topography, stiffness, shear stress and electrical forces) and biochemical factors (growth factors, genes or proteins). However optimal solutions to bone regeneration remain elusive. This review will focus on biological and physicommechanical considerations currently being explored in bone tissue engineering.

78 1. Introduction

79 Bone tissue regeneration remains an important challenge in the field
80 of orthopedic and craniofacial surgery. Traumatic injuries and various
81 pathological diseases, including osteoporosis, osteoarthritis, osteogenesis
82 imperfecta and Paget's disease, can impair normal bone functions
83 and lead to bone fractures non-unions, immobility, severe pain and de-
84 formity. As such the demand for bone grafts is considerable, and repre-
85 sents the second most common tissue transplantation procedure after
86 blood, with over 2.2 million bone graft procedures conducted world-
87 wide annually in orthopedics and dentistry [1]. Current clinical treat-
88 ments for large defects are challenging, and despite the natural
89 capacity of bone for healing, if an injury is beyond a critical limit (critical
Q9 size defect), it cannot heal by regeneration. (See Tables 1–3.)

91 Harvesting bone from autologous or allograft donor sites is an ex-
92 pensive and painful procedure, which is linked with added health
93 risks associated with additional surgical procedures in elderly patients,
94 increased risk of infection or disease transmission or rejection from do-
95 nors [2,3]. Novel solutions are required to overcome the limitations of
96 current bone grafting approaches and in vitro strategies, through tissue
97 engineering or regenerative medicine approaches, which are promising
98 strategies for treating bone diseases and reconstructing bone defects.

99 Tissue engineering approaches involve the combination of cells, bio-
100 material scaffolds and specialized culture conditions incorporating bio-
101 chemical and physical stimuli to encourage in vitro bone formation. The
102 development of responsive biomaterials capable of producing modulat-
103 ed function in response to the dynamic physiological and mechanical
104 environments in vivo remains an important challenge in bone tissue en-
105 gineering to achieve long-term repair and good clinical outcomes [4].
106 Despite considerable progress in the understanding of the biological
107 and physicomechanical properties of organs and tissues, relatively few
108 orthopedic biomaterials designed with biomimetic and bioresponsive
109 characteristics have been translated into clinical solutions to date [5].
110 Nevertheless, according to the EU-Report on Nanotechnology, the glob-
111 al market for 'smart biomaterials' reached \$47 billion in 2009 and will
112 rise to \$113 billion by 2025 [6].

113 Most current orthopedic technologies draw on simple or composite
114 building blocks, yet next-generation tissue-engineering strategies in
115 bone regeneration must combine multiple functions such as drug re-
116 lease, receptor recognition, environmental responsiveness and tuned
117 biodegradability [7]. Furthermore, traditional medical devices lack

biomimicry, and mismatches in tissue morphology, or chemical and
mechanical properties ultimately accelerate implant failure [8,9]. In par-
ticular, current scaffold and implant designs are not biochemically, or
physically specific to a particular patient, and long-term or permanent
implants are not ideal for many applications, due to risks of stress
shielding [10,11] and implant loosening [12]. Biomimetic approaches
to biomaterial design enable molecular, structural and biological com-
patibility similar to that of the tissue being replaced to facilitate the re-
generation of complex tissues [13–15]. Multiple stimuli have been
proposed as principal contributors or mediators of cell activity and
bone tissue formation, including physical (substrate topography, stiff-
ness, shear stress and electrical forces) and biochemical factors (such
as growth factors, genes or proteins). However, next-generation scaf-
folds and tissue engineered constructs need to be driven by a personal
medicine approach and must integrate a range of biological and physical
properties for optimal bone regeneration.

2. Structural and functional elements of bone tissue

Bone tissues can be understood as a nanocomposite 3D scaffold of
nano-HA and type-I collagen and can be principally defined as either
cortical or cancellous bone, dependent on the structural organization,
porosity and mechanical properties. Cortical bone (<20% porosity) con-
sists of close packets of osteons, cylindrical (Haversian) systems with a
central channel that consists of a blood vessel surrounded by concentric
rings (lamellae) of bone matrix. The mechanical properties of this sys-
tem are anisotropic, being a function of the direction of applied force
($E = 20$ GPa along the Haversian system and $E = 8$ GPa along the trans-
verse axis) [16,17]. In contrast, cancellous bone is less dense (>90% po-
rosity) and is structured in plates (trabeculae) offering a larger surface
area to mass ratio, making it an effective structure for ion exchange (ho-
meostasis), hematopoiesis, and imparting flexibility in load-bearing
bones ($E = 100$ MPa) [18]. Within the osteon and cancellous bone ma-
trices are complex networks of canaliculi, which connect bone cells (os-
teocytes) and are believed to play an important role in traducing
mechanical stresses, arising from every day from physical loading, into
a cellular biochemical process to regulate bone remodeling a process
known as mechanotransduction [19,20].

Bone tissue is a highly specialized and hierarchical connective tissue
with structural, cellular organization and component material proper-
ties that direct bone function. The bone architecture is under continuous
