Dry eye  
Carboxymethylcellulose  
Liposomal spray  
Sodium hyaluronate  
Randomised control trial  
Artificial tears

### ABSTRACT

**Purpose:** To assess dry eye treatment with four preservative-free dry eye artificial tear treatments to facilitate evidence-based prescribing.

**Methods:** A randomised, single masked crossover trial of Clinitas Soothe, Hyabak, Tears Again and TheraTears artificial tears was conducted on 50 symptomatic dry eye patients, aged  $60.8 \pm 14.2$  years. At baseline and after trialling each treatment for 4 weeks, signs and symptoms were assessed using the Ocular Surface Disease Index (OSDI), non-invasive tear break-up time, fluorescein tear break-up time, tear meniscus height (TMH), Phenol Red test, lid-parallel conjunctival folds (LIPCOF), ocular surface staining, and lipid layer grading and osmolarity (baseline visit only).

**Results:** OSDI ( $p = 0.002$ ), LIPCOF ( $p = 0.014$ ) and conjunctival staining ( $p < 0.001$ ) significantly improved from baseline, however, the impact of each dry eye treatment on ocular symptoms and signs was similar. Clinitas Soothe and Hyabak were preferred by 34%/30% of participants, but only subjective comparison with the other drops influenced this choice. TheraTears was preferred (by 24%) by those with a lower baseline tear volume ( $p = 0.01$ ) and Tears Again (by 12%) by those with a thinner baseline lipid layer ( $p = 0.04$ ). The treatment that afforded the greatest improvement in clinical signs did not consistently match each individual's preferred treatment.

**Conclusions:** If prescribed to a general dry eye population, the artificial tears performed similarly, improving symptoms and conjunctival signs. However, osmolarity balanced artificial tears were the preferred treatment in individuals with low baseline tear volume and liposomal spray for individuals with a baseline lipid layer deficiency.

### 1. Introduction

Dry eye signs and symptoms are typically triggered by a dysfunction of the ocular tear film, which may arise due to deficiencies in the aqueous phase of the tear film (termed aqueous-deficient dry eye) and, more commonly, the lipid phase of the tear film (termed evaporative dry eye) [1]. The primary course of dry eye treatment is topical application of eye drops, gels and sprays to re-build and stabilise the tear film. Numerous compositions of dry eye treatments are commercially available, principally differing in which element of the tear film they primarily aim to replace. Sodium hyaluronate is a glycosaminoglycan with viscoelastic properties [2] that increases tear film stability [2–4] and promotes epithelial cell migration [5,6]. Carboxymethylcellulose (CMC) is an anionic cellulose polymer with a carboxylic group, which exhibits a high affinity for bioadhesion [7], increases tear film stability [3] and promotes epithelial cell migration [8]. Liposomal dry eye

treatments consist of phospholipids, which enhance the lipid tear film layer [9] and also increase tear film stability [9–11]. Osmolarity is considered a key driver of ocular surface damage from dry eye [12] and an artificial tear has been formulated to overcome this but this has not been extensively tested clinically against other treatment options [13]. Approximately 78% of dry eye patients have been reported to have lipid layer deficiencies [1], therefore Lee and colleagues recommended liposomal sprays should be the first choice of treatment for all dry eye patients [14]. However previous studies tend to compare the benefit of one 'class' of artificial tear, with perhaps saline as a control, some over short durations, rather than cross class to inform optimum prescribing decisions (Table 1).

Despite knowing that artificial treatment individually helps to reduce symptoms compared to a saline placebo, evidence-based criteria indicating which composition of treatment is best suited to alleviate particular dry eye signs and symptoms are currently unavailable. The
