9 **Abstract.**

10 The aerosol layers during the heat wave of July 2015 over Paris Area have been studied using
11 a N₂-Raman lidar with co- and cross-polarized channels. The lidar observations are examined to
12 allow the identification of main aerosol types and their origins, in synergy with measurements of the
13 AERONET sunphotometer network and back trajectory studies from the HYSPLIT model. The
14 results are compatible with spaceborne observations of MODIS and CALIOP. As for previous heat
15 waves of August 2003 and July 2006 occurring in France, the aerosol optical thickness is very large,
16 up to 0.8 at the lidar wavelength of 355 nm (between 0.5 and 0.7 at 550 nm). However, air mass
17 trajectories highlight that the observed aerosol layers may have multiple and diverse origins during
18 the 2015 heat wave (North America, Northwest Africa, Southern and Northern Europe). Biomass
19 burning, pollution and desert dust aerosols have been identified, using linear particle depolarisation
20 ratio, lidar ratio and analysis of back trajectories initiated at the altitudes and arrival times of the
21 plumes. These layers are elevated and are shown to have little impact on surface aerosol
22 concentrations ($PM_{10} < 40 \mu g m^{-3}$ or $PM_{2.5} < 25 \mu g m^{-3}$) and therefore no influence on the local air
23 quality during the 2015 heat wave, unlike in 2003 and 2006. However, they significantly modify the
24 radiative budget by trapping part of the solar ingoing/outgoing fluxes, which leads to a mean
25 aerosol radiative forcing close to $+50 \pm 17 W m^{-2}$ per aerosol optical thickness unit at 550 nm
26 (AOT_{550}) for solar zenith angles between 55 and 75°, which are available from sunphotometer
27 measurements. This value is smaller than those of the 2003 and 2006 heat waves, which are
28 assessed to be $+95 \pm 13$ and $+70 \pm 18 W m^{-2}/AOT_{550}$, respectively. The differences between the heat
29 wave of 2015 and the others are mainly due to both the nature and the diversity of aerosols, as
